NEGATIVE OUTCOMES OF ICT USE AT WORK: META-ANALYTIC EVIDENCE AND THE ROLE OF JOB AUTONOMY

Abstract

Individuals can improve their task performance by using information and communications technology (ICT). However, individuals who use ICT may also suffer from negative outcomes, such as burnout and anxiety, which lead to poorer performance and well-being. While researchers have studied the positive outcomes of ICT use in the aggregate, the same has not been done for negative outcomes. This study uses a meta-analysis to examine the relationship between ICT use and negative outcomes, and the influence of job autonomy, or the level of discretion an individual has in conducting his/her job, on ICT use and the negative outcomes of ICT use. Job autonomy is relevant because a higher level of job autonomy allows individuals to decide how, how often, and when they will use ICT that is causing negative outcomes for their work. The results of the meta-analysis revealed that ICT use increased negative job outcomes and that, unexpectedly, autonomy exacerbated this effect. The paper concludes with a discussion of the possible reasons for this finding and suggestions for future research.

Keywords: ICT, job stress, strain, burnout, job autonomy, meta-analysis

1 Introduction

Organizations use information and communications technology (ICT) to improve their handling of information. Doing so enhances their ability to manage customers, processes, knowledge, and performance, and makes organizations more effective (Mithas, Ramasubbu, & Sambamurthy, 2011; Ray, Muhanna & Barney, 2005; Tanriverdi, 2005). However, individuals have also encountered negative outcomes when they use ICT. Examples include the increased number of interruptions to their work, making them less productive and more stressed (Fonner & Roloff, 2012), and the relatively poor quality of online versus face-to-face interactions (Kock, Lynn, Dow, & Akgün, 2006), which has led to resistance from customers who prefer physical, not virtual, support from retailers (Bitner, Brown, & Meuter, 2000).

While the negative consequences of ICT use on employees' work experiences have been widely studied (Robey & Boudreau, 1999), the results are not straightforward. For example, ICT use in organizations is related to stress, strain, and burnout (Day, Paquet, Scott, & Hambley, 2012; Lee, Chang, Lin, & Cheng, 2014; Nam 2013), because it places demands on employees, such as the need to respond more quickly and learn new ICT systems, as well as a possibly increased workload. In contrast, other researchers have found that ICT use may not result in negative job outcomes such as exhaustion, distress, or stress (Chesley 2005; Kraan et al., 2014; Sardeshmukh et al., 2012). The overarching goal of this paper is to resolve these inconsistent findings by examining the relationships between the constructs used to assess negative job outcomes and those used to capture IT use, which incorporate the actual use of a range of different ICTs.

The second goal of this paper draws from the phenomenon of employee discretion. The tension between the benefits and impositions of ICT use has led to employees directing their own work through attempts to make work related decisions and regain freedom in how they do their jobs (Avgar et al., 2010). Being able to decide how your job is done is referred to as "job autonomy"

(Hackman & Oldman, 1976), and this paper argues that job autonomy can ameliorate the negative impacts of ICT use. This argument builds on the findings that high job control negatively buffers the relationship between high job demands and strain (Karasek, 1979), and may reduce the impact of job stressors (Jones & Fletcher, 1996). Although the role of job autonomy and its related terms, such as job control, have occasionally appeared in some studies as a moderator, mediator, or predictor of the relationship between ICT use and negative work outcomes, the concept tends to be included in an ancillary, as opposed to a focal, role.

More broadly, the concepts of ICT use, negative work outcomes, and job autonomy have not been well-integrated in the literature, and the paper's second goal is to provide a framework for doing this. Employees who have higher levels of control and autonomy over various aspects of their job may be able exert more influence over potentially stress-provoking areas of their workplace (Day, Scott, & Kelloway, 2010). Similarly, the extent to which negative outcomes are experienced by individuals when they use a particular ICT for their work varies by the level of job autonomy they have. For example, employees with more control over how they do their job may decide to forego that specific technology and use an alternative one to accomplish their tasks, thus alleviating the negative outcomes. Even if there is no alternative technology, such employees could diminish the potential negative outcomes by perhaps spending more time to learn how to use the ICT in a way that makes the negative outcomes less likely.

The research questions this paper asks are: 1) what is the overall impact of ICT use on employees' negative job outcomes? and 2) what is the impact of autonomy on the relationship between ICT use and the negative outcomes of ICT use? A key challenge with these questions is that the focal constructs (ICT use, negative outcomes of ICT use and autonomy) have been measured in the literature with a variety of related constructs. To answer the research questions, we carry out a meta-analysis of the literature on the negative outcomes of ICT use and adoption and run

a meta-regression analysis to examine the moderating role of job autonomy. The study has two contributions. First, the study summarizes research on the range of negative outcomes experienced by individuals when they use ICT in a work context, enabling us to assess the state of research in this field. Second, it evaluates how job autonomy moderates the relationship between ICT use and negative job outcomes.

The next section introduces the transactional theory of stress (Lazarus & Folkman 1984), and the paper continues by using this theory to frame the prior literature on the negative effects of ICT use on individuals. We then describe the meta-analysis methodology and after presenting the results, the paper concludes with a discussion of their implications and suggestions for future research.

2 Theoretical Conceptualization

ICT has begun to influence a wider range of jobs, going beyond the automation of manual and routine tasks to complementing non-routine and analytical tasks (Autor, Levy, & Murnane, 2003). The increasing virtualization of organizational processes (Overby, 2008) has meant that members of occupations that had previously seen themselves as being immune from being replaced by computerization, such as public administration, teaching, and legal and accounting services, are less certain of that now (Hecker, 2005; Messersmith, Garrett, Davis-Kean, Malanchuk, & Eccles, 2008). In such an environment, the negative impacts of ICT use are being felt more frequently by an increasing number of individuals (Day et al., 2010). These effects are broadly centred on the increased level of stress felt by ICT users. In this section, we begin by providing an overview of the transactional theory of stress, a widely-used framework for understanding stress.

2.1 Transactional Theory of Stress

The transactional theory of stress is a well-known framework for understanding job stress (Lazarus, 2006), and has been used to conceptualize negative job outcomes perceived by employees, such as work stress, strain, distress, and work exhaustion (Crawford, Lepine, & Rich, 2010; Boswell et al., 2004; Elliot, Chartrand, & Hakins, 1994; Fox & Stallworth, 2010; Webster, Beehr, & Love, 2011). Stress is viewed as a complex cognitive, affective, physiological, and behavioural process in response to stimuli that are perceived to be threatening or harmful (Lazarus, 1990; Lazarus, 2006). This theory implies that stress is not directly created by environmental conditions, but instead depends on how an individual perceives and interprets threatening or challenging situations, and determines how to respond to those situations. The potentially harmful stimuli are called “stressors” (Jex & Yankelevich, 2008) and the maladaptive psychological, physical, and behavioural responses of individuals to these stimuli is termed “strain”, “distress”, and “work exhaustion”. Examples of stressors are workload, interpersonal conflict, lack of personal control, and organizational constraints.

The psychological strain variables that have been frequently investigated are distress and work exhaustion (Boswell, Olson-Buchanan, & LePine, 2004). Distress is the result of a negative perception of the

demand placed on a person and occurs if the levels of stress exceed the person's physical and psychological capacity (Selye, 1964; Selye, 1987). Psychological distress describes moods and emotions that occur intentionally, and have no specific referents (Bagozzi, 1999; Frijda, 1986). Psychological distress encompasses evaluative components, (e.g. "good-bad" and "like-dislike"), the presence of symptoms associated with depression, such as sadness, restlessness, and nervousness (Beaudry & Pinsonneault, 2010; Chesley, 2005), or emotional states experienced by individuals, such as boredom, fatigue, and anxiety (Carayon-Sainfort, 1992; Day et al., 2012; Eastin, Glynn, & Griffiths, 2007). Work exhaustion¹ or job burnout is defined as the physical, emotional, and mental exhaustion characterized by physical depletion, feelings of helplessness and hopelessness, emotional drain, and the development of negative self-concept and attitudes toward work, life, and people (Pines & Aronson, 1981). Burnout is caused by long-term involvement in demanding situations (Kilpatrick, 1989; Leiter & Maslach, 2003; Leiter & Schaufeli, 1996; Lu, Barriball, Zhang, & While, 2012; Moore, 2000a, 2000b; Zhang, Wang, Wu, Zhu, Bu, You, Liu, Zheng, Fang, Lu, lv, Ma, & Wanget, 2014).

A key underlying cause of work stress for employees is a changing work environment (Jex & Yankelevich, 2008). Work environments have changed in numerous ways over the past decades since information and communication technology (ICT) emerged; for example, the boundaries of employees' roles (Day et al., 2012) have shifted, as well as the flexibility in how they do their work (O'Driscoll, Brough, Timms, & Sawang, 2010). Employees have been exposed more frequently to new ways of accomplishing tasks, making it likely that they will experience one or more of these: changes in their workload, increased time pressure, physical and psychological conflicts, or heightened uncertainty beyond their capabilities (O'Driscoll et al., 2010; Thomee, Harenstam, & Hagberg, 2012). Drawing upon transactional theory, Day et al. (2010) argue that the extent to which the new work conditions that ICT imposes are perceived as taxing and exceeding employees' resources will determine how intensely employees view ICT as being negative and harmful. Therefore, it is likely that the use of ICT and the related physical and psychological efforts employees expend on tackling ICT-caused changes will lead to negative job outcomes, such as strain or stress. Thus, this meta-analysis uses transactional theory to examine the effects of technology use on employees' experiences of negative job outcomes.

2.2 Negative Work-Related Outcomes of Technology Use

Table 1 lists studies where ICT use in the workplace has been shown to have negative impacts on employees. ICT use reinforces the impression among employees that they need to work harder and faster, contributing to a perception that they are overloaded with work (Chesley, 2010; Tarafdar et al., 2011). In such a situation, employees may find it difficult to recognize the useful aspects of technology, which, in turn, results in them experiencing stress. For example, frequently checking email at work causes employees to experience stress (Kushlev & Dunn, 2015). Employees who use laptops or mobile devices to carry out work-related activities usually report work-related stress (Goldfinch, Gauld, & Baldwin, 2011; Nam, 2013).

(2012) and Nam (2013), focused on different types of ICT. ** K is the number of studies *** The plus and minus signs indicate whether the correlation between ICT and negative job outcomes is positive or negative. **** "Overall ICT use" refers to the types of ICT whose names were not mentioned in studies.				

IS research on the negative effects of the technology use has also paid attention to psychological distress and strain. For example, Beaudry and Pinsonneault (2010) considered the array of emotions, such as anger, anxiety, excitement, and happiness, that employees experience in response to ICT artefacts. Strain describes how much employees feel overwhelmed by the use of ICT at work (Chesley, 2014). Examples of psychological strain include user error, user frustration and aversive stress reactions (Coyle & Gould, 2002; Konradt, Christophersen, & Schaeffer-Kuelz, 2006; Otter & Johnson, 2000). Stress, strain, and distress can be created by work overload, role ambiguity, and role conflict (Goldfinch et al., 2011; Tarafdar et al., 2014; Tarafdar et al., 2015). Employees feel overloaded at work when their job demands exceed their limits (Leiter et al. 2003) and have to do too much in too little time with too few resources (Moore & Love, 2005). Technologies have been found to increase work overload; for example, email systems can distract employees from their work because they are afraid of missing important information that they would be accountable for if they do not respond to emails or check for them frequently (Barley, Meyerson, & Grodal, 2011).

Role ambiguity and role conflict can also create stress, and may be the result of adoption of technology. For example, the adoption of sales force automation technologies may increase the ambiguity of employees' roles, making them more complicated (Rangarajan, Jones, & Chin, 2005). Role conflict occurs when employees have to decide between using their time to learn a new ICT system and carrying out their routine duties. Technology alters employees' normal tasks, and if something wrong occurs, it is difficult for them to undo and return to essentially the same conditions in the original tasks to make a new decision. Role ambiguity depends on the extent to which employees increase the effort they spend learning how to integrate technology into their routine tasks, and how to confront the uncertainties associated with the process of learning technology (Day et al., 2012; Zigurs & Buckland, 1998). Work overload, role ambiguity, and role conflict are also related to employee burnout or work exhaustion (Leiter & Maslach, 2003, 2009; Leiter & Schaufeli, 1996; Moore, 2000a). Work exhaustion, both emotional and physical, has been studied in several occupations, such as physicians, technologists, social service workers, and teachers (Kilpatrick, 1989; Leiter & Maslach, 2003; Leiter & Schaufeli, 1996; Lu et al., 2012; Moore, 2000a; Zhang et al., 2014). The intensive use of technology has also been found to be positively related to burnout, in the form of exhaustion, reduced personal accomplishment, and depersonalization (Schaufeli, Keijsera, & Miranda, 1995). Schaufeli et al. (1995) found that nurses working at intensive care units (ICUs) where technology was used more intensively were more likely to experience burnout symptoms.

2.3 Managing the Negative Outcomes of ICT Use

While the use of technology has been found to be positively linked to increases in employees' distress, strain, and stress, this effect can be ameliorated if employees are free to decide the best ways to match the new ICT to their routine tasks (Beaudry & Pinsonneault, 2010; Day et al., 2010; Konradt, Christophersen, & Schaeffer-Kuelz, 2006; Messersmith, 2007; Nam, 2013; Sauter, Gottlieb, Jones, Dodson,

& Rohrer, 1983)². Strain or stress can be managed by enhancing the extent to which employees have a great deal of discretion, job control, and autonomy in making job-related decisions to get their work done. Jex & Yankelevich (2008) assert that job-related discretion is influential in reducing negative job outcomes. Drawing on various models proposed in the literature, such as the job demand control model (Karasek, 1979), the effort-reward model (Siegrist, 1996), and job demands-resources model (Bakker & Demerouti, 2007), job control (e.g., skill discretion and decision latitude) and job resources (e.g., autonomy) are the most important factors that reduce the impact of stress creators on employees' negative job outcomes (e.g., strain). Autonomy, job control, and job-related decision making can be used as facilitators to encourage employees to engage in using technologies and to buffer the relationship between technology use and negative job outcomes (Day et al. 2010; Day et al. 2012).

2.4 Autonomy

Autonomy is “the degree to which the job provides substantial freedom, interdependence, and discretion to the individual in scheduling the work and in determining the procedures to be used in carrying it out” (pg. 258, Hackman & Oldham, 1976). Other terms related to autonomy include job control (Day et al., 2012) and decision latitude (Korunka & Vitouch, 1999), which refers to the breadth of possibilities of decisions regarding action steps, the content of goals and plans, and time frames (Zapf, 1993), and empowerment, which refers to sharing power or giving more responsibility and autonomy to subordinates (Kirkman & Rosen, 1999). A lack of autonomy affects employees' job attitudes and causes them to experience work overload and burnout (Lee, Song, Cho, Lee, & Daly, 2003; Maslach & Jackson, 1981; Moore, 2000b; Pines & Aronson, 1983).

Researchers on the role of autonomy in technology use (Table 2) have reported that autonomy and a lack of job control are positively associated with technology use (Ahuja & Thatcher, 2005; Kraan et al., 2014; Sardeshmukh, Sharma, & Golden, 2012). For example, professionals who perceive no control over the conditions, processes, procedures, or contents of their work are less keen to use electronic medical records (Walter & Lopez, 2008). Conversely, employees whose managers or work environments support autonomy are more confident about continuing to use the Internet or computers than employees who work within environments that are more controlling (Roca & Gagné, 2008). Much research has concluded that a lack of autonomy is problematic for employees experiencing work stress when adopting new software or dealing with current ICT systems. At the same time, employees with greater autonomy may have lower levels of work stress: they may find it easier to set aside time to learn the features of newly-adopted applications or new technology upgrades, or be able to use ICT-based flexible work options (Day et al., 2012; Esmaeilzadeh & Sambasivan, 2012; Kraan et al., 2014; Sambasivan, Esmaeilzadeh, Kumar, & Nezakati, 2012). Research on autonomy has also shown that negative job outcomes that results from technology use are mitigated when employees have freedom in their work-time schedule, access to adequate resources, and control over work-related tasks (Ahuja & Thatcher, 2005; Chesley, 2014; Salanova, Llorens, & Cifre, 2013).

Table 1. Studies of Autonomy and Technology Use

Lack of Control	Video Display Terminal	1	+	Lindstrom et al., 1997
Job Schedule Control	Computer, Internet, Mobile phone	1	+	Chelsey, 2010

² In most workplaces, some ICTs are mandatory in certain job roles or to complete certain work tasks, while other ICTs can be used voluntarily at the discretion of individual workers. However, even in contexts where the use of a certain ICT is imposed or made compulsory, users may have some latitude in how they use it; for example, they may use it in a limited or surface manner, instead of infusing it into their work practices. To incorporate this range of understandings of the concept of “ICT use”, its use in this paper covers both mandated and voluntary use contexts.

Legend: * K is the number of studies ** The plus and minus signs indicate whether the correlation between ICT and negative job outcomes is positive or negative				

Autonomy has also been found to reduce the negative impacts of technology use on employees, such as work exhaustion, work overload, psychological distress, role ambiguity, role conflict, and psychological strain (Table 3) (Ahuja & Thatcher, 2005; Day et al., 2012; Kraan et al., 2014; McKnight, Phillips, & Hardgrave, 2009; Shen & Gallivan, 2004). Kraan et al. (2014) view perceived autonomy as a standardization mechanism, which can modify and control the effects of computer use on employees' work stress. Higher autonomy enables employees to arrange a more proportionate division of work, use less coercive methods, and organize tasks to ameliorate the negative effects of computer use. Autonomy also supports learning about technology, encourages a healthy environment, and undermines work stress when new features are introduced. When ICT professionals are provided with autonomy, they carry out their work independently, resulting in a lower incidence of work exhaustion (Ahuja et al. 2007). Likewise, autonomy interacts with the level of work overload, so that employees with greater autonomy do not feel overburdened in having to find novel ways to use ICT (Ahuja & Thatcher, 2005).

Table 3. Studies of Negative Job outcomes, Autonomy and Technology Use

Technology	Negative Job Outcomes	Relationship with Technology Use*	Role of Job Autonomy	Study	N
Computer Use	Stress	-	Moderator (negative)#	Kraan et al., 2014	18,723
ICT Use	Workload	+ , -		Ahuja & Thatcher, 2005	263

2.5 Summary

ICT use has been linked to a range of negative outcomes in a variety of work contexts, as discussed above. The growing prevalence of ICT indicates that these negative outcomes will be experienced by more individuals over time. The increased incidence of such negative outcomes may dampen the potential advantages that organizations may gain from their ICT investments. It is thus worth assessing the overall strength of this effect using a meta-analytic assessment. Figure 1 illustrates the theoretical framework proposed for this study. In this framework, ICT use is studied as both overall ICT use and specific ICT use, autonomy as employees' own efforts, initiatives, and decisions towards ICT use, and stress as any individual responses to stressful situations caused by ICT use.

Figure 1. Theoretical Framework

The goals of this study are to provide a meta-analytic review of the negative outcomes of ICT use and to examine the impact of job autonomy on ICT use and negative job outcomes. Doing so will bring together two different streams of research on ICT use in the workplace. Examining the overall progress that has been made in this field would also help to suggest directions for future study.

3 Methodology

A set of meta-analyses were utilized to synthesize the findings from prior research on the negative outcomes that individuals experience when using technology at work. A meta-regression was also performed to assess the impact of the moderating role of autonomy-related constructs, including job autonomy, job control, and decision latitude, on the relationship between ICT and negative job outcomes, such as stress, strain, distress, and exhaustion. Mixed-effects meta-regression was employed to analyse mean levels of autonomy-related constructs as the continuous variables in the consideration of the presence of residual heterogeneity. Meta-analysis is a quantitative approach for aggregating findings from individual studies that study similar research questions (Hunter & Schmidt, 2004). Compared to a narrative review of a field, the advantage of meta-analysis is to reconcile conflicting results across studies to understand the strength of the variables' underlying relations and causalities (Hunter & Schmidt, 2004). Meta-analysis has been used by information systems scholars to review topics as diverse as ICT-business strategic alignment (Gerow, Grover, Thatcher, & Roth, 2014), ICT turnover intentions (Joseph, Ng, Koh, & Ang, 2007), ICT innovation adoption (Lee & Xia, 2006), IS implementation success (Sharma & Yetton, 2003), and firm-level ICT payoff (Kohli & Devaraj, 2003). By combining results across studies, meta-analysis also "rescues" data-sets that would normally not be considered for analysis because they had a small sample size or insignificant results that did not warrant publication in a journal (Rosenthal & DiMatteo, 2001). Meta-analysis is useful because it helps overcome methodological issues, such as sampling error and poor reliability of measures, which may have dampened the relationship between the variables being studied. This meta-analysis followed Hunter and Schmidt's (1990) recommendations and the study was conducted in line with these steps: 1) Identifying and selecting relevant studies, 2) Coding variables from the samples, and 3) Performing the statistical meta-analysis.

3.1 Literature Search

Our goal was to identify empirical studies on the impacts of technology use on negative job outcomes, including stress creators (role ambiguity, role conflict, and workload), burnout (exhaustion, depersonalization, and reduced personal accomplishment), psychological distress, and strain. We also searched for studies on ICT use and negative job outcomes to find out how job autonomy (including its related terms) influenced either ICT use or work-related negative job outcomes, as well as the relationship between ICT use and negative job outcomes. Following established practice in prior meta-analytical studies (Dulebohn, Bommer, Liden, Brouer, & Ferris, 2011; Jackson et al., 1985; Podsakoff, Podsakoff, MacKenzie, Maynes, & Spoelma, 2014), the literature search process began by searching electronic databases, such as ScienceDirect, JSTOR, Scopus, Web of Science, Springer Link, EBSCO Host, ACM Digital Library, IEEE Explore, Google Scholar, and Emerald. This was done from March 2015 to March 2016. The keywords used to search for “ICT use” were: information technology use, information and communication technology use, and information technology adoption, while the keywords used for negative outcomes were: exhaustion, depersonalization, reduced personal accomplishment, psychological distress, stress, and strain. These search terms for stress creators were: role ambiguity, role conflict, and workload. For job autonomy, these search terms were used: autonomy, decision latitude, discretion, job control, and empowerment. These search procedures yielded a total of approximately 208 relevant studies.

3.2 Study Selection

To make our review robust, certain criteria were used to exclude irrelevant studies from the initial pool. First, studies that used non-employee respondents were also excluded, as this study focuses on ICT use at work. Second, qualitative and conceptual studies were dropped from the pool. Third, studies that examined the negative impact of ICT use but did not measure ICT use specifically (such as Ragu-Nathan, Tarafdar, Ragu-Nathan, & Tu, 2008; Tarafdar et al., 2007; Tarafdar et al., 2011) were excluded. Studies were included in the meta-analysis if their data collection instrument had at least one item that measured the extent of technology use. Fourth, studies that only focused on physical discomfort, such as the quantity of sleep (such as Lanaj, Johnson, & Barnes, 2014) or the state of an individual’s physical health (such as Mino, Shigemi, Tsuda, Yasuda, & Bebbington, 1999), were omitted. Finally, studies were included in the meta-analysis only if they reported their sample size, the reliability or composite reliability indices, and correlation coefficients, and included a correlation matrix. In addition, attempts were made to overcome the “file drawer problem” by sending a request for unpublished manuscripts on this topic to IS World, a popular mailing list for IS academics. Two studies were received after making that request, but they were not relevant to this study as they were not quantitative studies. The final sample consisted of 50 journal papers and two conference papers.

3.3 Coding Variables

A meta-analysis was conducted using the formulae developed by Hunter et al., (1982) for a total of 13 constructs: seven negative job outcomes (Table 4), four autonomy-related constructs, and two constructs for ICT use. The two constructs for ICT use were: overall ICT use and specific ICT use. “Overall ICT use” incorporates studies that did not specifically name the type of ICT that was used (Ahuja & Thatcher, 2005; Ayyagari, Grover, & Purvis, 2011; Beam, Kim & Voakes, 2003; Chesley, 2014; Compeau & Higgins, 1995; Fuglseth & Sørenbø, 2014; Schaufeli et al., 1995). “Specific ICT use” was used to classify studies which indicated the use of a particular ICT, such as “computer”, “email”, “mobile phone” (devices that receive or transmit voice calls and text messages only), “internet”, “smartphone” (internet-connected devices with high-resolution touch screens), “Electronic Data Processing” (EDP), and “Video Display Terminal” (VDT). Table 5 delineates seven indicators of ICT use which have been long argued across the literature as a source of employees’ negative work experiences.

To clarify the role of autonomy, we searched the sample of studies for papers that also investigated the role of autonomy. Among the 52 studies in the sample, we identified 137 relationships between the use

of various technologies, negative job outcomes, and stress creators, and 36 relationships where autonomy affected the level of technology use among employees. Within these 36 relationships, autonomy's role differed: it acted as a moderating, mediating, independent, or control variable. **Before analyzing the data, we excluded variables that were studied only once, and were thus understudied and did not fit the criteria for running a meta-analysis (Joseph et al., 2007), such as discretion and empowerment.** One variable, EDP use, was found only in one study (Table 5) but it was retained because data had been collected from three samples in the same study (Korunka & Vitouch, 1999). For each study, the following information was collected: sample size, the reliability of constructs (as reported using Cronbach's alpha) and correlation(r) or standardized regression coefficient (β) for each pair of relationships.

Table 4. Average Reliability Estimates for Independent and Dependent variables

Variable	K [#]	N [@]	Reliability(α)
<i>Negative Job Outcomes</i>

Legend: K is the number of samples for which reliability estimates were available; N is the total number of respondents across the K samples. p<0.05*, p<0.01**, p<0.001*** # Some studies studied more than one specified type of ICT.			

The variety of terms related to negative job outcomes, such as strain, distress, and work exhaustion, are conceptualized in the literature as individual responses to stressful situations; given that, stress is regarded in this study as a complex rubric rather than a simple variable (Lazarus et al., 1985). Therefore, stress refers to the operation of many variables which reveal processes of how individuals cognitively, affectively, and behaviorally respond to ICT-caused changes. Job autonomy is also similarly considered to be a rubric variable that encompasses the operation of job control and decision latitude (Hackman & Oldham, 1976). In this study, work stress is composed of seven negative job constructs, and the autonomy-related constructs are autonomy, job control and decision latitude.

3.4 Analysing Data

To analyse the data, we used the Comprehensive Meta-Analysis package (Borenstein et al., 2009) and ran a meta-regression analysis in R (Chen & Peace 2013). A corrected population correlation ρ was estimated for each pair of relationships, based on the reported correlation coefficients r or standardized regression coefficients β and sample size. Following Hunter and Schmidt (2004), we corrected correlations for sample error and for measurement error.

First, we used the index of reliability of independent and dependent variables to compute the artefact multiplier (A^4) for each study:

$A = \sqrt{r_{xx}} \sqrt{r_{yy}}$, where r_{xx} represents the reliability coefficient for the independent variable, and r_{yy} represents the reliability coefficient for the dependent variable.

Second, according to Hunter and Schmidt (2004), the corrected observed correlation for measurement error (r_c) can be calculated by:

$r_{ci} = r_i / A_i$, where r is the correlation between the independent and dependent variables reported in studies and obtained from the strength of the relationship between each pair of independent and dependent variables, A represents the artefact multiplier, and i refers to different studies.

Third, we calculate the sample size weights that take into account both sample sizes (N) and artefact multipliers (A) across studies:

$W_i = N_i A_i^2$, where N is the sample size of each study, (i) demonstrates the different studies, and A is the artifact multiplier for each study.

Finally, we determined the population estimate corrected (ρ), computing the corrected observed correlation (r_c) and weighted sample size (W) to account for sampling error and measurement error for each pair of variables. The formula for ρ is:

$\rho = \Sigma W_i r_{ci} / \Sigma W_i$, where W is the weighted sample size of each study, (i) refers to the different studies and r_c is the corrected observed correlation for measurement error for each study.

³ EDP use is measured with three different sample sizes in Korunka and Vitouch's (1999) study.

⁴ The artefact multiplier (A) is the ratio of the attenuated to the unattenuated effect and describes the impact of the artefact on the effect size. It is called an artefact multiplier because the magnitude of the observed (attenuated) effect size is equal to the (artefact multiplier) multiplied by (the unattenuated effect size) (Borenstein et al., 2009).

4 Results

The results of the meta-analyses are presented on Tables 6, 7, and 8, and the results of meta-regression analysis in Table 9. All tables report the sample size, the number of studies, population correlation (ρ), the 95% lower and upper confidence intervals and p-value. Table 6 demonstrates the impact of overall ICT use on work stress. Using Cohen's (1992) guidelines on effect size intervals, the meta-analysis results supported a significant relationship between ICT use and work stress. The average magnitude of the correlations of ICT use and work stress reflected a small effect size ($\rho = 0.07$).

Table 6. Overall ICT Use and Stress

Independent Variables	Dependent Variables	N	K	ρ	95% Confidence Interval		p-value
					Lower limit	Upper limit	
ICT Use	Work Stress	35337	34	0.07***	0.031	0.103	0.000

4.1 Overall Technology Use and Different Negative Job Outcomes

Table 7 shows the relationships between ICT use and distinct negative job outcomes. The variable "ICT use" was created by grouping studies on specific technologies with studies that did not mention any particular technology, such as studies on "ICT use" or "ICT systems use". The results indicate that ICT use is significantly correlated with stress ($\rho = 0.20$, $p\text{-value} = 0.000$), workload ($\rho = 0.15$, $p\text{-value} = 0.000$), and role conflict ($\rho = -0.50$, $p\text{-value} = 0.000$). Although the relationship between ICT use and stress and workload is positive, the relationship between ICT use and role conflict, a stressor, is negative. For other negative job outcomes, the meta-analysis showed that the effects were ambiguous, as the confidence intervals for each of them included zero.

Table 7. Impact of Overall Technology Use

Independent Variables	Dependent Variables	N	K	ρ	95% Confidence Interval		p-value
					Lower limit	Upper limit	
ICT Use	Negative Job Outcomes						
	Stress	31193	16	0.20***	0.106	0.291	0.000
	Strain	5553	4	-0.03	-0.093	0.148	0.652

4.2 Different Types of Technology Use and Negative Job Outcomes

Table 8 depicts the impact of using particular technologies on negative job outcomes, such as stress, distress, strain, and workload. Except for the relationship between EDP use and stress, and VDT use and distress, all of the technologies had a positive effect on negative job outcomes. However, only the use of email, internet, VDT, and smartphones were significantly related to negative job outcomes. The meta-analysis results indicated that the average magnitude of the correlations of computer use showed a small effect size across studies with stress, psychological distress and workload, and did not support a significant relationship between computer use and stress, psychological distress, and workload. Email use was found to have a highly significant relationship with stress (p-value=0.000), and a small effect size with stress ($\rho = 0.28$). Also, email use had a significant relationship with distress (p-value=0.009) and workload (p-value=0.012), and reflected a small effect size with distress ($\rho = 0.10$) and workload ($\rho = 0.28$).

The relationships between internet use and both independent variables, stress and strain, were significant (p=0.008 and p=0.001), with a small effect size ($\rho = 0.26$ and $\rho = 0.18$), respectively. Smartphone use was strongly related to stress (p-value =0.000), with a large effect size ($\rho = 0.87$), while its relationship with burnout ($\rho = 0.42$, p-value =0.003) and workload ($\rho = 0.36$, p-value =0.009) was significant and had a medium effect size. Analyzing the effect of relationships that different IS systems have on negative job outcomes, only VDT use yielded a significant relationship with workload (p-value =0.006) with a medium effect size ($\rho = 0.38$).

Table 8. Negative Job Outcomes Resulting from the Use of Specific Technologies

Independent Variables	Dependent Variables	N	K	ρ	95% Confidence Interval		p-value

EDP Use	Workload	608	1	0.05	-0.075	0.178	0.402
VDT Use	Distress	477	2	-0.07	-0.272	0.144	0.533

VDT Use	Workload	144	1	0.38**	0.114	0.597	0.006
Legend: K is the number of samples for which reliability estimates were available; N is the total number of respondents across the K samples. p<0.05*, p<0.01**, p<0.001***							

4.3 Autonomy

Table 9 depicts the results of the meta-regression analysis on the moderating role of autonomy on the relationship between ICT use and negative job outcomes. While autonomy significantly moderated the relationship between ICT use and work stress ($\beta=0.111$, p-value=0.038), the relationship was in the opposite direction from the one that was expected. In other words, instead of demonstrating that autonomy mitigated the level of work stress among employees using ICT, the findings revealed that, as the level of autonomy increased, the effect of ICT use on work stress increased. 13.6 percent of the variance in the correlations between ICT use and work stress can be explained by the level of autonomy.

Table 9. Moderator Analysis of the Level of Autonomy

Level of Autonomy	N	K	se	t-value	β	95% Confidence Interval		p-value
						Lower limit	Upper limit	
ICT Use → Work Stress	23409	27	0.051	2.192	0.111*	0.007	0.216	0.038*

5 Discussion

This paper clarifies the effect of ICT use on employees and the negative challenges and experiences they deal with by incorporating the power of multiple primary empirical studies via a meta-analysis. Also, this study provides an insight into the moderating role of job autonomy in which job autonomy appears as an amplifier to further augment the levels of stress among employees using ICT. Our findings show the extent to which technology use has a negative impact on employees, the different consequences that may occur, and how autonomy influences the occurrence of these effects. The results are discussed in the following sections in detail.

Figure 2. Summary of Relationships between ICT Use, Job Autonomy and Stress

5.1 Impact of ICT use on work stress

This study shows that using ICT creates work stress, supporting research which has demonstrated that ICT use is related to negative job outcomes, such as strain, distress, or work exhaustion (Day, Paquet, Scott, & Hambley, 2012; Lee, Chang, Lin, & Cheng, 2014; Nam 2013). This meta-analysis included

studies that had general measures of the use of ICT (see Tables 1 and 4), as well as those that measured specific technologies such as smartphones or the Internet (see Tables 1 and 5). When the results are aggregated across all of the different technologies used by employees, the results of the meta-analysis indicate that ICT use was significantly correlated with stress and workload, as well as a stressor, role conflict.

5.2 The effects of different types of ICTs

5.2.1 Computer Use

In prior studies, some researchers indicated that employees using computers experience stress, distress (e.g., anxiety), and an increase in their workload (Carayon-Sainfort, 1992; Chesley, 2005, 2010; Thomée et al., 2012), while other researchers revealed that working with computer-based technologies did not lead to employees stress or distress (e.g., anxiety) (Compeau & Higgins, 1995; Goldfinch et al., 2011; Kraan et al., 2014). The results of our meta-analysis support the latter view.

5.2.2 Email Use

Our meta-analysis results support the findings of prior studies that receiving and sending emails causes employees to feel stressed and distracted (Barley et al., 2011; Kushlev & Dunn, 2015; Thomée et al., 2012). Employees who receive or send a high number of work-related emails may spend most of their working hours checking or replying to these emails, which creates stress, psychological distress and a high volume of work overload for them.

5.2.3 Mobile Phone Use

Some researchers found that employees who use mobile phones to receive or send calls and messages to accomplish their tasks experience stress or a high level of workload (Barley et al., 2011; Chesley, 2010; Nam, 2013). In contrast, several other studies found that the use of mobile phones by employees at their workplace does not lead to negative job outcomes (Thomée et al., 2012). The results of our meta-analysis did not find a significant correlation between mobile use and stress, and workload (Table 8). This finding supports the view that while employees are distracted during their working day when they answer mobile phones, this distraction is not significant enough to make them experience stress or work overload. Indeed, the extent to what using ICTs, such as computer and mobile phone, make employees feel overburdened or overloaded is determined by the frequency and broad features of ICT use (Chesley, 2010).

5.2.4 Internet Use

Some researchers point out that pervasive internet usage among employees makes them experience negative job outcomes, such as stress, strain, and workload. Some examples of such negative job outcomes created by internet usage are user errors, user frustration and aversive stress reactions (Chesley, 2010; Konradt et al., 2006; Nam, 2013). Our meta-analysis findings supported these results, and highlighted the small but significant link between Internet use and work stress and strain.

5.2.5 Smartphone Use

The meta-analysis results were consistent with previous findings that smartphone use increased work-related exhaustion and stress among employees (Derks, van Mierlo, & Schmitz, 2014; Lee, Chang, Lin, & Cheng, 2014). One of the most interesting findings of our study was that smartphone usage had the largest effect on some negative job outcomes, especially work stress. The results of our study may indicate that regularly using some technologies such as smartphones may lead to employees facing exhaustion daily and being psychologically detached at their workplace (Derks et al. 2014).

It is worth noting that individual experiences of ICT use change dramatically over time. Employees may find technology adoption stressful, but after some time, they become accustomed to the new ways of working with newly-adopted technologies. Thus, the use of ICTs whose life span is more than 20 years, and are thus no longer novel and innovative, cannot be stressful as before (Day et al., 2010). This explains why while employees do not feel stressful when using mobile phones and laptop or desktop computers, they do experience stress when using smart phones (Table 8).

5.2.6 Specific ICT System Use

Korunka and Vitouch (1999) found across three samples that working with electronic data processing (EDP) systems does not lead to employees experiencing stress, distress, or an increased workload. When the results from their three samples were meta-analyzed, their findings were supported, showing no overall effect of EDP use on negative job outcomes. Research on the use of video display terminals (VDT) had contradictory findings on whether employees were negatively affected by using them (Lindstrom et al., 1997; Sauter et al., 1983). While our results showed that VDT use was negatively correlated with distress, the only significant correlation was with workload, following Lindstrom et al. (1997) (Table 8). While the terms “VDT” and “EDP” systems may seem archaic now, their relevance for this study lies in them providing evidence of the impact of ICT on individual employees when such systems were in use in workplaces.

5.3 Autonomy

The second objective of this study was to measure the moderating impact of autonomy on the negative outcomes that employees face when they use technology. Prior research has shown that job autonomy, job control, and decision latitude are positively associated with ICT use, and negatively correlated with stress, strain, distress, and work exhaustion (Appendix A). This suggests that employees with greater autonomy, such as those who have access to additional resources or flexible work schedules, use ICT to the extent that they consider appropriate, after considering its potential negative impacts (Ahuja & Thatcher, 2005). While most studies have similarly found that autonomy buffers the relationship between ICT use and negative job outcomes (Chesley, 2014; Day et al., 2012), our findings indicate the opposite: that high levels of autonomy escalate work stress among employees using ICT. Although this result is surprising, it can be understood if we relate it to the properties of ICT systems at work. Gerten, Beckmann, & Bellmann, (2019) found that the complexities created by the implementation of ICT systems can constrain the strength of autonomy. ICT systems may contain features that enforce work routines which are different from those individuals with high levels of job autonomy prefer, increasing their workload. Instead of providing them freedom to choose the tools for their job, autonomy may increase the cognitive load they experience when they do their work. A less autonomous worker may be more receptive to the introduction of IT in their work practices, because it may reduce the occurrence of uncertainty and volatility in their workflows. Similarly, organizations sometimes use ICT to monitor their employees, so as to ensure the ICT is used appropriately and that they receive a reasonable return on their investment. This is also incompatible with the preferences of individuals with high levels of job autonomy. For them, the introduction of such systems may lead to a struggle in reconciling their differences with management in terms of the type of work environment they want to work in. Thus, while ICT use increases the stress faced by individual employees, those with higher levels of autonomy may be overburdened by a higher workload because of features of the ICT system that detract from autonomy rather than enhance it.

6. Implications and future research

Researchers have studied the negative effects of ICT use on employees (Tarafdar et al., 2007; Thomee, Dellve, Harenstam, & Hagberg, 2010; Thomée et al., 2012), and how these effects reduce employees' outcomes, such as technology-enabled behavioral performance and innovation (Tarafdar et al., 2014, 2015). By meta-analyzing the findings from 52 studies, our research has shed further light on the impact

of ICT on negative job outcomes (such as strain, psychological distress and work exhaustion) and stress creators (such as work overload, role ambiguity and role conflict). Before offering implications and potential avenues for future research, we present the limitations of our research.

6.1 Limitations

First, this meta-analytic study relied on the statistical results of many other studies to arrive at its findings. It is thus dependent on the quality of the prior studies. While we carried out the precautionary practices recommended for meta-analyses to avoid any possible biases, it is worth keeping in mind this intrinsic inadequacy of the meta-analytic method. Similarly, we did not include the results of case studies because of the requirements of meta-analysis.

Second, when selecting the sample, we did not specify any time period between the use of ICT and the occurrence of negative outcomes. The reason was that very few studies reported the time lag between the use of an ICT and when the negative outcomes were assessed. While some outcomes, such as an increased workload and exhaustion, may appear quickly after the introduction of an ICT, others, such as stress and burnout, may only manifest themselves after a certain time period. Thus, it is possible that the specific pattern of negative outcomes found in each study would have been affected by the gap between the use of the ICT and the measurement of negative outcomes.

Third, the changing nature of ICT, reflected in the variety of technologies studied (from VDTs to smartphones), reflects how ICT use has expanded from workplaces to family and other non-work contexts. While the study has aggregated results from studies over the past three decades, individuals are using technology more intensively and frequently now than in the past, and this may make it difficult to identify the source of the negative outcomes. For example, are negative outcomes more closely related to the use of ICT for managing family and personal activities, or for work routines? The general quickening in the pace of work and non-work life (Sonnentag, 2005) and the blurring of work-life boundaries (O'Driscoll et al., 2010) makes it difficult to disentangle the role of ICT use in exacerbating negative outcomes, such as stress and burnout.

6.2 Implications and Further Research

The results of this study point to the prevalence of negative outcomes from ICT use among individuals. Since outcomes such as increased workload may predict the extent to which individuals resist new systems (Laumer, Meier & Weitzel, 2016), future researchers should pay greater attention to the role of individual users in impeding the potential value that can accrue to organizations from the implementation of new systems. Such research can draw on studies of ICT use and system success (e.g. Sabherwal, Jeyaraj & Chowa, 2006), which link use-related and system-related constructs to system success, and extend the nomological network to include negative outcomes of ICT use.

One critical aspect would be to examine the accumulative impact of individually-felt negative outcomes. Marakas and Hornik (1996) view resistance as a means through which users express their disquiet with a potentially flawed system. From this perspective, stress is a precursor to resistance, with resistance being a withdrawal behaviour due to stress (Lapointe & Rivard, 2005). Given that the enactment of ICT use by interdependent individuals can be conceptually aggregated into collective system use (Burton-Jones & Gallivan, 2007), can the negative outcomes of individual ICT be summed in the same way, perhaps as "collective resistance"? This involves examining the conceptual nature of collective ICT-related negative outcomes: is it global, shared or configural, following the multilevel language of Kozlowski & Klein (2000)? Another avenue of research could be whether ICT-related negative outcomes form part of the switching costs from existing systems, which have been found to increase user resistance (Kim & Kankanhalli, 2009; Polites & Karahanna, 2012). This is particularly relevant as organizations are beginning to use digital technologies to dramatically reshape their business strategies in terms of the scope, scale, speed, and sources of business value creation (Bharadwaj, el Sawy, Pavlou, & Venkatraman, 2013).

As the digitization of work processes increases (Overby, 2008), understanding the match between an individual's work and ICT user roles becomes crucial for managing the level of negative outcomes they experience. Future researchers could also examine how these relationships differed when users participated in the implementation of an ICT, as that experience has been found to make them more satisfied with their ICT (Carayon & Karsh, 2000). Notions of organizational justice (Colquitt, Conlon, Wesson, Porter, & Ng, 2001) and equity (Joshi, 1991) could be applied to better understand the link between participation and the manifestation of negative outcomes from ICT use.

Research on ICT use, the negative outcomes of ICT use, and autonomy indicates that further investigation in this domain is necessary to extricate the competing effects of ICT. For example, ICT may make individual users more autonomous while also increasing their workload and their dependence on the technology (Carayon & Karsh, 2000). While the benefits of autonomy have been extensively discussed among researchers, the results of this study call for further investigation to examine how being autonomous through ICT would be related to negative job outcomes that employees experience. This combination of consequences is potentially exacerbated if we view individual users as social actors, who draw on resources, such as relationships in professional and social networks, to overcome negative outcomes when they are encountered (Lamb & Kling, 2003). The increased autonomy brought about by ICT implies a decrease in the need to interact with others while performing one's job duties, weakening the existence of such networks and their role as organizational ballast. Future researchers could draw on the job demand-control (Karasek, 1979), the effort-reward (Siegrist, 1996), and the job demands-resources models (Bakker & Demerouti, 2007) to examine the relationship between ICT use, autonomy, and negative job outcomes.

This points to a further direction for research: integrating the positive and negative outcomes of ICT use to examine how they complement or offset the motivation to continue using an ICT. Researchers could investigate whether user satisfaction and perceived usefulness can co-exist with stress, increased workload, and role conflict. If so, how do individuals reconcile these opposing outcomes? Are there any common predictors for these outcomes? The findings of this study and future research in this area will be useful for designers of ICT systems. Designers will receive guidance as to how they can design systems not just to achieve the desired outcomes, but also avoid the undesirable ones (O'Driscoll et al., 2010). At the organizational level, our findings motivate the need for more empirical research on the tension between individual and organizational responses to the deployment of new technologies.

A possible research model that can be developed for future research is the application of autonomy and its related terms as to how employees cope with the shock of the adoption of new ICTs. Despite the importance of the role of employees' perceived values in comparing switching costs and benefits when they decide to adopt new ICTs (Mahmud, Ramayah, & Kurnia, 2017), a new set of autonomy-related constructs can ameliorate disruptive behaviours that employees often show at their workplace. In broader contexts in which employees are more likely to feel constrained by the advent of a new generation of ICTs, organizations need to put in more effort to understand the role of autonomy through which employees can experiment with their own designed subsystems while also using externally-provided IT services (Vithayathil, 2018). Organisations may choose to establish portals for employees to communicate with the organization about their interaction with new ICTs, so they can learn more about difficult-to-use systems, or involve employees in making decisions about investing and deploying complex systems. Had employees been given such an avenue, organisations may have achieved better outcomes with their new ICT adopting projects, rather than facing resistance or disinterest. Therefore, this study calls for research to conceptually and empirically provide insights into the motivating and inhibiting roles of autonomy in enhancing ICT use, while mitigating its negative impacts simultaneously.

5 Conclusion

This meta-analytic study supports the link between technology usage and negative job outcomes. As the technologies used in organizations have changed from VDTs to smartphones, these negative effects have occurred in parallel with improvements in work outcomes. Contrary to the prevailing literature and our expectations, job autonomy and its similar terms amplified the negative impacts of ICT use. The

results of the meta-regression analysis suggested that autonomy-related constructs increase the levels of stress employees experience when using ICT. The study's results point to the need to develop a more integrated nomological network of the outcomes of ICT use, incorporating both negative and positive outcomes, across both individual and organizational levels. The results also demonstrate the clear need for future researchers to consider the influence of the research contexts on their results. Taken together, these actions will contribute towards our collective understanding of the impact of ICT in organizations.

Appendix A: Relationships between ICT Use, Autonomy-related constructs, and Negative Job Outcomes

Negative Job Outcomes	Relationships*	Aspect of Job Autonomy	Relationships*	Technology	Studies	N
Stress	+	Decision Latitude as a predictor	-	Electronic data processing (EDP)	Korunka & Vitouch, 1999	608
	-	Job Control as a predictor	+	ICT Use	Day et al., 2012	244
	+	Autonomy as a predictor	+,-	Internet and mobile Use	Nam, 2013	850
Strain	-	Autonomy as a control variable	+	ICT Use	Chesley, 2014	2,242
	-	Job Control as a predictor	-	ICT Use	Day et al., 2012	244
Distress	-	Job Control as a predictor	-	ICT Use	Day et al., 2012	244
	-	Autonomy as a control variable	+	ICT Use	Chesley, 2014	2,242
Exhaustion	-	Job Control as a predictor	-	ICT Use	Day et al., 2012	244
	-	Autonomy as a mediator	+	ICT Use	Saradeshmukh, Sharma, & Golden, 2012b	417
Workload	-	Job Control as a predictor	-	ICT Use	Day et al., 2012	244
	-	Job Schedule Control as a predictor	+	Computer, Internet, and Mobile phone	Chelsey, 2010	1667
	-	Autonomy as a predictor	+	ICT Use	Salanova et al., 2013	1,072
	-	Lack of Control as a predictor	+	Video Display Terminal (VDT)	Lindstrom et al., 1997	144
Role Ambiguity	-	Job Control as a predictor	-	ICT Use	Day et al., 2012	244
	-	Autonomy as a predictor	+	ICT Use	Salanova et al., 2013	1,072
Legend: N is the total number of respondents in each study. *The plus and minus signs indicate whether the correlation between ICT and negative job outcomes is positive or negative.
