Abstract

Previous studies have suggested cerebro-cerebellar circuitry in working memory. The present fMRI study aims to distinguish differential cerebro-cerebellar activation patterns in verbal and visual working memory, and employs a quantitative analysis to determine lateralization of the activation patterns observed. Consistent with Chen and Desmond's (2005a,b) predictions, verbal working memory activated a cerebro-cerebellar circuitry that comprised left-lateralized language-related brain regions including the inferior frontal and posterior parietal areas, and subcortically, right-lateralized superior (lobule VI) and inferior cerebellar (lobule VIIIA/VIIB) areas. In contrast, a distributed network of bilateral inferior frontal and inferior temporal areas, and bilateral superior (lobule VI) and inferior (lobule VIIB) cerebellar areas, was recruited during visual working memory. Results of the study verified that a distinct cross cerebro-cerebellar circuitry underlies verbal working memory. However, a neural circuitry involving specialized brain areas in bilateral neocortical and bilateral cerebellar hemispheres subserving visual working memory is observed. Findings are discussed in the light of current models of working memory and data from related neuroimaging studies.

Keywords Cerebellum · Cerebrocerebellar · Functional magnetic resonance imaging · Verbal working memory · Visual working memory

Introduction

Working memory may be conceptualized as a neural system that temporarily maintains, stores, and manipulates information for complex cognitive tasks such as reasoning, learning, and language comprehension (Baddeley and Hitch, 1974). Within the theoretical framework, mechanisms of the phonological loop and visuo-spatial sketchpad are thought to support verbal and visual working memory, respectively.

Data from neuroimaging studies have consistently demonstrated the involvement of left inferior frontal and left inferior parietal regions in verbal working memory, areas of the brain that have been linked to phonological rehearsal and storage, respectively (Cohen et al., 1994, 1997; Awh et al., 1996; Fiez et al., 1996; Braver et al., 1997; Fiez and Raichle, 1997; Smith and Jonides, 1998; Jonides et al., 1998). Although cerebellar activations were also observed in early neuroimaging studies (Paulesu et al., 1993; Petrides et al., 1993; Jonides et al., 1997), their exact function in verbal working memory was not well understood (see Jonides et al., 1997).

In a previous fMRI study, Desmond and colleagues (1997) identified two cerebellar regions that were differentially activated during verbal working memory: one located bilaterally in the superior hemisphere (lobule VI/Crus I), and another in the inferior aspect (lobule VIIIB) of the right hemisphere. Based on the canonical cortico-ponto-cerebellar network (Middleton and Strick, 2001; Kelly and Strick, 2003) that forms a closed

1 loop circuitry via the thalamus (Thach and Jones, 1979; Asanuma et al.,
2
3 1983; Middleton and Strick, 1997a; for review see Ramnani, 2006), the
4
5 authors proposed a cerebro-cerebellar model of verbal working memory to
6
7 account for superior cerebellar contribution to phonological rehearsal and
8
9 encoding and inferior cerebellar contribution to phonological storage
10
11 processes. In a later event-related fMRI study, Chen and Desmond
12
13 (2005a) found concomitant activation of the superior cerebellum and left
14
15 frontal regions during encoding, and concomitant activation of the right
16
17 inferior cerebellum and left parietal regions during maintenance,
18
19 supporting earlier speculations that a lateralized left cortical-right
20
21 cerebellar neurocircuitry supports verbal working memory.
22
23
24
25
26
27

28 Although the laterality effect was observed in a number of
29
30 subsequent studies (Chen and Desmond, 2005b; Kirschen et al., 2005,
31
32 2010; Marvel and Desmond, 2010), a caveat was that hemispheric
33
34 lateralization was assessed via visual comparison of the number of
35
36 activated voxels and activation intensity (as indicated by the normalized Z
37
38 value) in homologous brain regions, without the rigour of statistical testing.
39
40 To address this, one of the objectives of the present study was to evaluate
41
42 the laterality effect of verbal working memory by means of a laterality index
43
44 measurement (Binder et al., 1995; Cuenod et al., 1995; Desmond et al.,
45
46 1995; Gaillard et al., 1997), which statistically evaluates voxel *beta*-values
47
48 of homologous regions of interest. Specifically, an unbiased threshold-free
49
50 computation of voxel *t*-values within regions of interest was used to
51
52 calculate the laterality index. This approach has been shown to minimize
53
54
55
56
57
58
59
60
61
62
63
64
65

1 computational biases that are associated with statistical thresholding
2
3 (Matsuo et al., 2012; for review see Seghier, 2008).
4
5

6 Another objective of the present study was to verify the laterality
7
8 effects of working memory processes in the visual system. In the animal
9
10 literature, an abundance of neurophysiological evidence converged on the
11
12 involvement of ventral prefrontal and occipitotemporal brain areas in
13
14 pattern, object, and face recognition and recall (Wilson et al., 1993; Miller
15
16 et al., 1991, 1996; Rainer et al., 1998; Scalaidhe et al., 1999; Rolls, 2000).
17
18 These results are in good concordance with studies demonstrating visual
19
20 recognition deficits in monkeys with ventromedial prefrontal cortex and
21
22 inferior temporal cortex lesions (Passingham, 1975; Mishkin and Manning,
23
24 1978; Bachevalier and Mishkin, 1986; Horel et al., 1987). Findings from
25
26 human lesion (for review see Farah, 1990; Owen et al., 1995, 1996;
27
28 Newcombe et al., 1987; Muller et al., 2002; Milner, 2003) and
29
30 neuroimaging (Courtney et al., 1997; Haxby et al., 2000; Postle et al.,
31
32 2000; for review see Ungerleider et al., 1998; Ranganath and D'Esposito,
33
34 2005) studies also provide evidence for the involvement of the
35
36 abovementioned brain regions in visual working memory. However,
37
38 despite the wealth of data, it remains unclear whether or not cerebral
39
40 hemispheric lateralization persists in processes underlying visual working
41
42 memory.
43

47
48
49
50
51

52 While there have been reports of left mid-frontal region
53
54 preponderance during object working memory tasks (Smith and Jonides,
55
56 1995; Smith et al., 1995), there are by far more evidence for supporting
57
58
59
60
61
62
63
64
65

right cerebral dominance during visuo-spatial working memory tasks (McCarthy et al., 1994; Haxby et al., 1995; Courtney et al., 1996; Walter et al., 2003; van Asselen et al., 2006; Thomason et al., 2010; Yamanaka et al., 2010; for review see Mottaghy, 2006; Suchan, 2008). The inconsistent laterality effects observed at the neocortex prevail at the cerebellar level, with a number of studies reporting left cerebellar dominance during face (Haxby et al., 1996; Koshino et al., 2008), spatial (Gruber and Yves von Cramon, 2003), and abstract object (Hautzel et al., 2009; Kang et al., 2011) working memory tasks, and to a lesser extent, preponderance of right cerebellar activations during visuospatial working memory tasks (Pessoa et al., 2002; Thurling et al., 2012).

Given the inconsistency in previous findings, the current study aims to determine if laterality topography exists for working memory in the cerebrum and cerebellum for verbal and visual stimuli through a quantitative analysis.

Materials and Methods

Participants

Forty two (22 males, 20 females) neurologically healthy young-adults took part in the study. Their age ranged from 21 to 31 years with a mean of 22.83 years (S.D. = 1.95 years). All the subjects were right-handed (Laterality Quotient (LQ) > 60) according to Edinburgh Handedness

Inventory (EHI LQ: Mean = 96.83, S.D. = 6.14; Oldfield, 1971). The study protocol was approved by the Nanyang Technological University Institutional Review Board and the National Healthcare Group (NHG) Domain Specific Review Board (DSRB)(A). The experimental procedures were carried out in accordance with the 1964 Declaration of Helsinki. At the successful completion of the experiment, subjects were paid for their participation. Informed consent was obtained from individual subjects prior to the start of each experiment.

Task description

We employed a block design for two working memory tasks (visual and verbal), based on the Sternberg paradigm. The tasks were presented to the subjects in alternating blocks of high- and low- load in separate runs. Each cycle consisted of 1 block of high-load and 1 block of low-load that had 2 trials each. Each block was interleaved by a 1.6 seconds interval and block duration was 20s. There were 10 cycles in each run adding up to a total of 20 high-load and 20 low-load trials. Each run lasted 400s. 2 runs of each task were performed and task order was counterbalanced across subjects.

Stimuli were pseudo-randomly presented on a Fujitsu Lifebook computer (Fujitsu, Tokyo, Japan) with E-Prime version 2.0 (Psychology Software Tools, Inc, Pittsburgh, US) software. The images were projected onto a screen that was located at the back of the scanner bore, and subjects viewed them via a mirror mounted on the cage coil. Before the

1 experiment began, subjects practised the tasks to familiarize with the
2
3 experimental procedures.
4
5

6 In the verbal working memory (VERWM) task, a red fixation cross
7
8 indicating the start of a trial was presented in the middle of the screen for
9
10 1.2 seconds. Following that, a horizontal array of either six non-repeated
11
12 letters (high-load condition) or six identical letters (low-load condition) was
13
14 presented above the cross for 3 seconds. During this time, subjects
15
16 rehearsed the letters in sequential order subvocally and continued to do so
17
18 during a 3 seconds maintenance period where no stimuli were shown on
19
20 the screen. After the maintenance period, a probe letter was presented for
21
22 2 seconds and the subjects determined if it matched one of the letters in
23
24 the array by pressing a button under the right index finger for “match” and
25
26 a button under the right middle finger for “not-match”.
27
28
29
30
31
32

33 In the visual working memory (VISWM) task, the same fixation
34
35 cross preceded (1.2 seconds) the presentation of a horizontal array of
36
37 either three non-repeated geometrical patterns (high-load condition) or
38
39 three identical geometrical pattern (low-load condition). During a 4
40
41 seconds encoding phase, subjects viewed and retained the visual patterns
42
43 in their mind and continued to do so during a 1.5 seconds maintenance
44
45 period where no stimuli were shown on the screen. After the maintenance
46
47 period, a probe pattern was presented below the cross for 2.5 seconds
48
49 and the subjects determined if it matched one of the patterns in the array
50
51 by a button press in the same manner as that in the VERWM task.
52
53
54
55
56
57
58 Subjects were instructed not to use verbal strategies for the VISWM task.
59
60
61
62
63
64

In both the verbal and visual working memory tasks, duration of a single trial was 9.2 seconds (see Figure 1).

Figure 1 about here

Behavioural data analysis

Paired-samples t-tests evaluated within-condition (high load versus low load) differences in performance accuracy and reaction times.

MRI data acquisition

Whole-brain MRI data were acquired on a 3 Tesla scanner (Siemens Trio, Erlangen, Germany) equipped with a 32-channel array coil. To minimize movements, foam paddings were placed between the subject's head and scanner's head rest. The acquisition protocol consisted of localizer, structural, and functional scans. High resolution (1mm isotropic) T1-weighted images were acquired in the sagittal plane with magnetization prepared rapid acquisition gradient echo sequence. T2*-weighted echo planar images were acquired in the oblique axial plane with the following parameters: TR = 2500 ms; TE = 29 ms; 48 slices; flip angle = 90°; FOV = 225 mm; 64 x 64 matrix giving an in-plane voxel size of 3.5 x 3.5 mm²; slice thickness = 3.5 mm. The acquisition plane was rotated 25° with respect to the posterior vertical axis of the brainstem to optimize signal measurements from the cerebellum and neocortices (Chen and Desmond,

2005b). MRI data collection was synchronized with the behavioural task via interfacing with the E-Prime software. Prior to each run, subjects were provided instructions via the scanner's intercom system.

Functional data analysis

fMRI data were analyzed using the Statistical Parametric Mapping (SPM8) software package (Wellcome Department of Cognitive Neurology, Institute of Neurology, University College London, UK, www.fil.ion.ucl.ac.uk/spm). Structural and EPI images were aligned to the AC-PC plane. An 'interleaved bottom-up' slice timing correction was applied to the EPI images to correct for temporal lags in image acquisition. Head motions were corrected by aligning EPI images of run 1 and run 2 to the first EPI image of run 1. This routine generated a mean EPI image, which was used as a source image for registering the realigned functional images to the individual subject's anatomical T1 image.

The experimental effects were estimated with the general linear model within SPM8. Two [high-load > low-load (VERWM); high-load > low-load (VISWM)] contrast images were calculated for each subject, yielding 42 images per task. It was assumed that these contrast images reflected parametric recruitment of neural resources during the two load conditions. The images were then normalized separately to fit the ICBM152 whole-brain template with default parameters in SPM8 and the Spatially Unbiased Infra-tentorial Template (SUIT). This was done to overcome the limitations of normalizing cerebellar activations to MNI space. Accordingly, the MNI template, which is derived from 152 T1-weighted scans, lacks

1 information of important anatomical landmarks (e.g. primary and
2 intrabiventer fissures) crucial for aligning structures in the cerebellum. It
3 has been previously suggested that such a normalization procedure would
4 result in substantial stretching of the cerebellum in the z-direction,
5 'pushing' activations in superior aspect of the cerebellum to the visual
6 cortices and obscuring those in the inferior cerebellum (Diedrichsen, 2006;
7 Diedrichsen et al., 2009).

18 In the SUI normalization, individual T1-weighted images were
19 cropped to isolate the cerebellum from the other brain structures. These
20 structural images were then warped to fit the SUI space and the resulting
21 deformation parameters were applied to the functional images for
22 resampling at 3.5 x 3.5 x 3.5 mm³ resolution. All contrast images were
23 smoothed with a 6 mm Full Width Half Maximum (FWHM) Gaussian
24 kernel.

36 After normalization, random effects analyses were conducted on
37 task-specific contrasts with one-sample t-tests. Cluster-level activations
38 that survived family-wise error (FWE) rate correction with significance level
39 at $p < 0.05$ were reported. Except for cerebellar activations that were
40 superimposed onto the SUI template, all other brain activations were
41 superimposed onto the MNI template. Locations of cerebral and cerebellar
42 activation maxima were determined using the Automated Anatomical
43 Labeling [AAL; (Tzourio-Mazoyer et al., 2002)] software and probabilistic
44 cerebellar atlas (Diedrichsen et al., 2009), respectively.

Lateralization of brain activations was evaluated with AveLI (Matsuo et al., 2012). In this method, voxel *beta*-values are used to compute laterality index (LI) of two homologous regions of interest (ROIs). Specifically, subordinate LIs (sub-LIs) are computed from task-specific positive *beta*-values using the following equation:

$$\text{sub-LI} = \frac{L_t - R_t}{L_t + R_t}$$

where L_t and R_t are the summations of voxel *beta*-values at and above an arbitrary threshold in the left and right ROIs, respectively. AveLI is subsequently calculated by averaging the sub-LIs in the ROIs as follows:

$$\text{AveLI} = \frac{\sum(\text{sub-LI})}{VN}$$

where VN is the total number of positive *t*-values voxels in the ROIs.

In the current study, we used AAL template (Tzourio-Mazoyer et al., 2002) in Wake Forest University PickAtlas (Maldjian et al., 2003) and the SUI cerebellum template (Diedrichsen, 2006) to create bilateral ROIs for AveLI analyses in the cerebral cortex and cerebellum, respectively. Based on previous literature, ROIs for the VERWM task were defined in the inferior frontal gyrus (see Chen and Desmond, 2005a), inferior parietal lobule (see Ravizza et al., 2004), cerebellar lobule VI/CrusI, and cerebellar lobule VIIIB/VIII (see Chen and Desmond, 2005b). For the VISWM task, ROIs were defined in the inferior frontal gyrus (see Courtney et al., 1996), inferior temporal gyrus (see Ranganath et al., 2004), cerebellar lobule

VI/CrusI (see Thurling et al., 2012), and cerebellar lobule VIIB/VIII (see Hautzel et al., 2009).

Results

Behavioural data

In the VERWM task, performance accuracy (percent) was significantly ($t(40) = 5.55$, $P < 0.001$) higher in the low-load ($M = 98.90$, $SD = 1.94$) compared to high-load ($M = 95.24$, $SD = 4.18$) condition. Reaction times (milliseconds) were significantly ($t(40) = 16.51$, $P < 0.001$) greater during high-load ($M = 939.64$, $SD = 166.38$) compared to low-load ($M = 653.55$, $SD = 114.27$) condition. Similarly in the VISWM task, subjects registered significantly ($t(40) = 12.05$, $P < 0.001$) higher percentage of correct responses in the low-load ($M = 97.99$, $SD = 2.64$) compared to high-load ($M = 87.44$, $SD = 5.85$) condition. Reaction times (milliseconds) were significantly ($t(40) = 14.03$, $P < 0.001$) greater during high-load ($M = 864.07$, $SD = 165.07$) compared to low-load ($M = 699.56$, $SD = 142.56$) condition.

Across tasks, subjects performed better in the verbal task compared to the visual task ($t(40) = 7.02$, $P < 0.001$) although they took a longer time to make their responses ($t(40) = 4.10$, $P < 0.001$).

Imaging data

Activations in MNI space

Figure 2, Table 1, and Table 2 show regional activation profiles and loci of activation maxima during the working memory tasks.

In the VERWM task, left hemispheric dominance was observed in inferior and middle frontal regions, posterior parietal regions, and occipitotemporal regions. Apart from the brain regions depicted in Figure 2, other activated brain areas not visible from the rendered brain included the putamen, caudate, pallidum, insular, cingulum, and hippocampus.

In the VISWM task, brain activations were obtained bilaterally in the inferior and middle frontal regions, posterior parietal regions, occipital regions, and occipitotemporal regions. Activated brain areas not visible from the rendered brain included the cingulum, insular, hippocampus, and thalamus.

Figure 2 about here

Table 1 about here

Table 2 about here

Activations in SUIT space

Figure 3 and Table 3 show cerebellar activation profiles and loci of activation maxima during the working memory tasks, respectively.

Although the VERWM task appeared to recruit bilateral superior cerebellar regions, cluster-level thresholding produced activation maxima only in the right hemisphere. Within this region, two activation maxima were obtained; locus of the stronger maxima lay anterior, inferior, and lateral to the weaker one. In the same hemisphere, a separate activation maxima was obtained in lobule VIIB/VIII of the inferior posterior cerebellum. Of note, there was no significant cerebellar lobule VIIB/VIII activation in the left hemisphere.

In the VISWM task, robust activations were obtained bilaterally in the superior posterior region of cerebellar lobule VI, which became a contiguous cluster through the adjoining vermal activation in the anterior cerebellum. Smaller clusters of voxels were also obtained in the inferior posterior aspects of both cerebellar cortices. The intensity and size of the activation maxima in left cerebellar lobule VIIB was greater compared to that in the right hemisphere.

Figure 3 about here

Table 3 about here

AveLI

Table 4 shows the laterality effect of brain activations during the working memory tasks. According to Seghier (2008) and Matsuo et al. (2012), AveLI values greater than 0.2 and lesser than -0.2 represent left and right lateralization of brain activations, respectively.

A robust laterality effect was observed in the VERWM task. Activations in the IFG (0.32 ± 0.17 ; Mean $\pm$ SD) and IPL (0.59 ± 0.20) were lateralized to the left cortical hemisphere whereas those in lobule VI (-0.37 ± 0.40), lobule VIIB (-0.58 ± 0.45) and lobule VIIIA (-0.31 ± 0.41) were lateralized to the right cerebellar hemisphere. Activations in cerebellar lobule Crus I was bilateral.

In contrast, in the VISWM task, AveLI values approximating zero (-0.04 to 0.12) indicated that cortical (inferior frontal gyrus, inferior temporal gyrus) and cerebellar (lobule VI/CrusI and lobule VIIB/VIIIA) brain regions were quasi-equitably activated across hemispheres.

Table 4 about here

Discussion

The present study confirms earlier findings supporting a lateralized cerebro-cerebellar (left neocortical-right cerebellar) network of verbal working memory. In contrast, quantitative findings showed bilateral activations in the cerebral and cerebellar regions during visual working memory. These results did not provide evidence to suggest a distinct right neocortical-left cerebellar network for visual working memory.

The activations observed in the region representative of the Broca's area and posterior aspect of the left parietal cortex during verbal working memory are in concordance with previous findings (Chen and Desmond, 2005a, b; Paulesu et al., 1993; Cohen et al., 1997; Ravizza et al., 2004). Specifically, the left inferior parietal lobule (BA 40) has been linked to processes related to phonological storage. Although cluster maxima were obtained in the proximity of the Broca's area (see Figure 2, Table 1), the contrast images in the present study did not reveal any cluster maximum in the left inferior parietal lobule. However, based on laterality effect analysis that showed strong dominance of the left inferior parietal lobule (see Table 4), it is likely that this brain region might be part of a larger contiguous node that was localized to the superior parietal lobule (see Table 1). A number of previous investigations have observed superior parietal activations during verbal working memory (Petrides et al., 1993; Tsukiura et al., 2001; Crottaz-Herbette et al., 2004; Narayanan et al., 2005; Marvel and Desmond, 2012). While its exact function is unclear, the brain region is thought to be involved in the storage of verbal information

(Awh et al., 1996), memory retrieval (Callicot et al., 1999), and processes related to attentional demands (Smith et al., 1998). In the current Sternberg paradigm, it is likely that the subjects iteratively attended to the alphabets on the screen to subvocally rehearse the visual information for memory maintenance and storage. In general, our data are in agreement with current models of verbal working memory that hypothesize the contribution of the Broca's area to articulatory rehearsal and the posterior parietal region to phonological storage (Desmond et al., 1997; Chen and Desmond, 2005a), processes of which sustain the phonological loop assumed to be fundamental to the perception and production of language (Baddeley et al., 1988; Miyake and Shah, 1999; Baddeley, 2003).

Hellige (1993) and Banich (1997) proposed that hemispheric specialization of cognitive functions is innate in the human brain. A number of fMRI studies have reported dominance of the left cerebral hemisphere during verbal working memory tasks (Casey et al., 1995; Kelley et al., 1998; Golby et al., 2001) and right cerebral hemisphere during nonverbal working memory tasks (Thomas et al., 1999; Manoach et al., 2004). In these studies, hemispheric specialization was determined by either contrasting the activation maps of working memory versus control tasks (Casey et al., 1995; Thomas et al., 1999), spatial working memory versus object working memory tasks (Manoach et al., 2004), or verbal working memory versus nonverbal working memory tasks (Manoach et al., 2004). The results of these between-task contrasts informed us about the neural substrates that were uniquely activated or brain regions that were

1 activated more in extent and intensity in one task relative to the other. In
2
3 contrast, a within-task (high-load minus low-load condition) parametric
4
5 contrast reflects neural underpinnings of the task that was performed.
6
7 Previously, Thomason et al. (2008) had employed laterality index
8
9 measurement to determine hemispheric specialization of phonological loop
10
11 processes and found left cerebral lateralization in prefrontal and parietal
12
13 regions. In the present study, we compared high- and low-load verbal
14
15 working memory within-subjects and found not only left lateralization of the
16
17 aforementioned neocortical brain regions but also right lateralization of
18
19 cerebellar substrates in lobule VI and lobule VIIb/VIII. To our knowledge,
20
21 this is the first quantitative demonstration of a cerebro-cerebellar network
22
23 in verbal working memory, confirming findings of earlier studies that
24
25 implicated right-sided lateralization of cerebellar involvement in
26
27 phonological loop routines (Chen and Desmond, 2005 a, b; Kirschen et al.,
28
29 2005, 2010; Marvel and Desmond, 2010).

30
31
32 Studies of primates have shown that neural connections originating
33
34 from neocortical frontal regions terminate predominantly along medial
35
36 aspects of the pontine nucleus (Wiesendanger et al., 1979; Schmammann
37
38 and Pandya, 1997a, b), which in turn project to superior portions of the
39
40 cerebellar cortex including lobule VI and Crus I (Haines et al., 1997;
41
42 Middleton and Strick, 1997b, 2001; Dum and Strick, 2003; Kelly and Strick,
43
44 2003). A distinct circuitry originating from the parietal and temporal regions
45
46 has also been identified to synapse along lateral portions of the pontine
47
48 nucleus (Wiesendanger et al., 1979; Leichnetz et al., 1984; Weber and
49
50
51
52
53
54
55
56
57
58
59
60
61
62
63
64
65

1 Yin, 1984; May and Andersen, 1986; Brodal and Bjaalie, 1997), which in
2
3 turn project to inferior aspects of the paramedian lobule [(hemispheric
4
5 lobule VIIB); Brodal 1979, 1982; Glickstein et al., 1994]. Taking together
6
7 these findings and our current data, they form a strong neuroanatomical
8
9 and functional basis for implicating a crossed coupling between left inferior
10
11 frontal region and right superior cerebellar region in articulatory rehearsal
12
13 and a separate crossed coupling between left inferior parietal region and
14
15 right inferior cerebellar region in phonological store (Desmond and Fiez,
16
17 1998; Paulesu et al., 1993; Chen and Desmond, 2005 a, b; Salmon et al.,
18
19 1996; Rypma et al., 1999; Awh et al., 1996; Desmond et al., 1997; Smith
20
21 et al., 1998). Future research employing effective connectivity analysis
22
23 should provide insights into the integration between functionally
24
25 specialized brain areas.
26
27
28
29
30
31

32
33 Of note, our findings are not consistent with that of two recent
34
35 neuroimaging studies that reported the absence of cerebellar hemispheric
36
37 lateralization in verbal working memory (Hautzel et al., 2009; Thurling et
38
39 al., 2012). In the earlier study that employed an n-back paradigm (Hautzel
40
41 et al., 2009), subtraction analyses of 2-back minus 0-back yielded bilateral
42
43 cerebellar activation in lobule VI and lobule VIIIA/VIIB. It was argued that
44
45 the lack of cerebellar lateralization could be due to the nature of the n-back
46
47 task that emphasized manipulation of information and executive control in
48
49 excess of stimulus maintenance, thus superseding processes of the
50
51 phonological loop that might have been induced. Although reasonable, the
52
53 assumption did not prevail when a Sternberg paradigm emphasizing item
54
55
56
57
58
59
60
61
62
63
64
65

1 encoding and maintenance was used in a subsequent fMRI study
2
3 (Thurling et al., 2012). We suggest that the lack of cerebellar hemispheric
4
5 lateralization might be due to inequitable articulatory rehearsal between
6
7 the load conditions. In that study, high-load condition comprised a matrix
8
9 of six letters and low-load condition comprised a matrix of one letter and
10
11 five '#' symbols. In the latter condition, it is not reported whether the
12
13 subjects rehearsed subvocally only the letter or every item in the matrix
14
15 including the '#' symbols, or if they did rehearse at all during the
16
17 maintenance phase of the task. In the present study, the number of items
18
19 presented was identical across conditions and all items were alphabets
20
21 (see Figure 1) and subjects were asked to continue subvocal rehearsal
22
23 even during the maintenance phase. This, we reasoned has the effect of
24
25 equating motoric processes underlying articulatory rehearsal for encoding
26
27 and maintenance, without which subtraction analyses might elicit
28
29 additional cerebellar resources for motoric processes in the high-load
30
31 condition. Alternatively, the additional cerebellar activations might reflect
32
33 greater motoric demands for rehearsing different alphabets under the high-
34
35 load condition or response-time variability between the two conditions
36
37 (Simmonds et al., 2007).
38
39
40
41
42
43
44
45
46

47 While brain regions associated with motoric and cognitive functions
48
49 may be topographically located in the same cerebellar lobules (i.e. VI and
50
51 VIIb/VIII), meta-analytic data of Stoodley and Schmahmann (2009)
52
53 suggests a dissociation of functional locality. Accordingly, lobular VI and
54
55 VIIb/VIII activations associated with motoric processes are located anterior
56
57
58
59
60
61
62
63
64
65

(y coordinate between -60 to -70) to those that are associated with working memory (y coordinate between -70 to -80). Our data concur well with their findings in that two distinct regions of cerebellar lobule VI were activated during the verbal working memory task, i.e. one in the anterior aspect and another in the posterior aspect of the lobule (Table 3). Recently, Peterburs and colleagues (2015) were able to attribute a motoric cerebellar network to oculomotor demands and a separate load effect cerebellar network to memory demands during stimulus encoding. In the case of lobule VIIb/VIII, the activation was localized to the posterior aspect of the brain structure.

Apart from the phonological loop, working memory models have also envisaged a separate system (visuo-spatial sketchpad) that enables the human brain to hold and manipulate non-verbal information for deciphering semantic and geographical properties of objects in the environment (Andrade, 2001; Conway et al., 2007). As proposed by Baddeley and colleagues (Baddeley and Hitch, 1974; Baddeley, 1986; Logie, 1995), the visuo-spatial sketchpad comprises two mechanisms: an *inner scribe* for image rehearsal and a *visual cache* for storage, processes of which operate in tandem to support visual working memory. In a review of data from lesion and neuroimaging studies, Baddeley (2003) proposed candidate brain structures that might be involved in visuo-spatial working memory: for inner scribe, inferior frontal gyrus (BA 47), middle frontal gyrus, and a region overlapping the superior parietal lobule (BA 7) and anterior extrastriate occipital cortex (BA 19); for visual cache, inferior aspect of the occipitotemporal region and the cuneus (BA 17). The current

1 activations obtained in the aforementioned brain areas (see Table 2)
2
3 support Baddeley's conjecture and concur with data from animal
4
5 (Bachevalier and Mishkin, 1986; Horel et al., 1987), human lesion (Owen
6
7 et al., 1995, 1996; Newcombe et al., 1987) and neuroimaging (Haxby et
8
9 al., 2000; Postle et al., 2000) studies of visual working memory.
10
11
12

13 Although bilateral parietal activations were observed during visual
14
15 working memory (Figure 2b), only a maximum in the right superior parietal
16
17 lobule was revealed under the current thresholding (Table 2). Interestingly,
18
19 this brain area lies near the occipitoparietal region postulated by Baddeley
20
21 (2003) to be involved in inner scribe processes. While mechanisms of
22
23 these processes are not well understood, a parsimonious prediction would
24
25 be that visual imagery plays a part in keeping the stimuli in working
26
27 memory. A number of neuroimaging studies have demonstrated precuneal
28
29 activations, a component brain region of the superior parietal lobule,
30
31 during visual mental imagery (Kosslyn et al., 1993; Fletcher et al., 1995;
32
33 Ghaem et al., 1997; Ganis et al., 2004). Lundstrom and colleagues (2005)
34
35 further showed that these brain activities are related to accurate item
36
37 recognition and recall, coherent with the high accuracy scores in the
38
39 current study.
40
41
42
43
44
45
46
47

48 Apart from these brain regions, additional activations were also
49
50 obtained in the fusiform gyrus of the inferior temporal cortex (see Table 2),
51
52 as reported in a number of other investigations (Fuster and Jervey, 1982;
53
54 Miller et al., 1991, 1996; Postle et al., 2000). While its function is not as
55
56 clear-cut as those of the phonological loop, there is evidence to show that
57
58
59
60
61
62
63
64
65

1 the inferior temporal cortex is centrally involved in visual working memory,
2
3 as lesion or cooling of this brain region significantly impaired performance
4
5 of delayed matched to sample working memory tasks (Horel et al., 1987;
6
7 Gaffan and Murray, 1992; Newcombe et al., 1987).
8
9

10
11 Unlike the distinct laterality effect that was observed in the verbal
12
13 working memory task, we failed to obtain evidence for hemispheric
14
15 lateralization in visual working memory, as the contrast images revealed
16
17 activations in bilateral frontal and inferior temporal regions (see Figure 2),
18
19 and subcortically in bilateral superior and inferior cerebellar regions (see
20
21 Figure 3). The ‘zero-centering’ laterality indices confirmed that visual
22
23 working memory engaged specialized brain areas in both neocortical and
24
25 cerebellar hemispheres (see Table 4). Previous neuroimaging studies
26
27 have demonstrated the involvement of bilateral frontal and inferior
28
29 temporal brain regions in working memory of novel faces (Haxby et al.,
30
31 1995; Courtney et al., 1997), and more recently with event-related fMRI,
32
33 Ranganath and colleagues (2004) showed that active maintenance of
34
35 visual information is supported by activation of object representations in
36
37 inferior temporal cortices, and that memory retrieval is effected by top-
38
39 down signals originating from the frontal cortices. Therefore, lesions in and
40
41 along the pathway connecting these two brain regions would severely
42
43 impair visual recall (Eacott and Gaffan, 1992; Gutnikov et al., 1997;
44
45 Hasegawa et al., 1998; Tomita et al., 1999).
46
47
48
49
50
51
52
53

54
55 Consistent with our finding, two recent fMRI studies reported,
56
57 among other cerebellar areas, bilateral activation of lobule VI and lobule
58
59
60
61
62
63
64
65

1 VIIIB during working memory of abstract object (Hautzel et al., 2009;
2
3 Thurling et al., 2012). Of note, in the Thurling et al. (2012) study, stronger
4
5 lobule VI and lobule VIIIB activations were obtained in the right cerebellar
6
7 hemisphere. Through post-experiment feedback, the authors posited that
8
9 the use of verbal strategies might have activated the phonological loop,
10
11 thereby reducing demand of the visuo-spatial sketchpad. This may offer a
12
13 plausible explanation for the findings in our study. In a recent event-related
14
15 fMRI study, Sobzak-Edmans and colleagues (2016) reported that stored
16
17 visual representations could possibly involved maintenance mechanisms
18
19 that employ verbal coding. Alternatively, the quasi-equitable cerebellar
20
21 activations obtained in lobule VI and VIIIB might not be the result of
22
23 phonological loop recruitment but rather a reflection that a distributed
24
25 network is needed to support processes of the visuo-spatial sketchpad.
26
27 Cerebellar activations obtained in the midline vermal regions could be
28
29 associated with online oculomotor control (Takagi et al., 1998; Miall et al.,
30
31 2000; Krauzlis, 2005), as subjects in the current study might have made
32
33 saccadic eye movements from one geometrical pattern to another during
34
35 encoding.
36
37
38
39
40
41
42
43
44

45 Data from neurophysiological and behavioral experiments in
46
47 monkeys have shown that object recognition involves a multistage process
48
49 leading from localized feature analysis in the primary visual cortex, through
50
51 a sequence of association areas, to more global object recognition in the
52
53 inferior temporal cortex (Malach et al., 1995). This might explain why an
54
55 extensive recruitment of brain resources is needed to support processes of
56
57
58
59
60
61
62
63
64
65

not only object recognition but also memory retrieval. Alternatively, we could suppose that if subjects in the present study had chosen to remember the letter array in the verbal working memory task as a visual pattern, the same way visual stimuli were maintained in visual working memory, it is possible that an equally extensive bilateral network might have been activated. However, this process is cost intensive and the brain knowing of a more efficient system would convert the graphemes to phonemes before entering them into the phonological loop for encoding and maintenance, thus recruiting the left cerebro-right cerebellar network. We speculate that the lack of an alternative cost-effective system in visual working memory might have resulted in the extensive recruitment of bilateral neocortical and cerebellar structures.

The present study is not without limitations. First, similar to the trial setup of Thurling et al.'s (2012) study, timing and item parameters were differentiated across tasks to match for performance accuracy. Results from our pilot study showed that by increasing encoding and reducing maintenance timing, and reducing the number of items in the visual task, accuracy rate was comparable between the two tasks ($t(9) = 1.53$, $P = .16$). Of note, subjects in our pilot study did not receive practice prior to the behavioural experiment. In contrast, subjects practised the tasks until they attained eighty percent accuracy prior to fMRI scanning. We posit that additional exposure to the stimuli might have aided, to a greater extent, performance of the verbal task compared to the visual task, biasing the interpretation that the observed laterality effect was a consequence of task

1 difficulty. While that could be a plausible explanation, it is noteworthy to
2
3 highlight that behavioural confounds of disparate task performance have
4
5 been reported in previous studies (Nystrom et al., 1999; Gruber and von
6
7 Cramon, 2003; Chen and Mitra, 2009; Thurling et al., 2012), implicating
8
9 the difficulty of matching performance accuracy across different modality
10
11 of working memory.
12
13
14
15

16 Second, while the current analyses are sufficient for answering
17
18 questions about hemispheric lateralization in working memory, they lack
19
20 the temporal resolution for evaluating specific processes of working
21
22 memory. Future research employing fast event-related fMRI will help us
23
24 better understand underlying cerebro-cerebellar circuitry of encoding and
25
26 maintenance in human working memory.
27
28
29
30

31 In summary, the results of the present study provide quantitative
32
33 evidence for an underlying cerebro-cerebellar circuitry in verbal working
34
35 memory. As postulated in earlier studies (Chen and Desmond, 2005 b;
36
37 Kirschen et al., 2005, 2010; Marvel and Desmond, 2010), the phonological
38
39 loop recruited left-lateralized language-related brain areas in the inferior
40
41 frontal and posterior parietal regions, and right-lateralized cerebellar areas
42
43 in lobular VI and VIIIB/VIII regions. In contrast, a lack of hemispheric
44
45 dominance in visual working memory suggests that a distributed network
46
47 of brain areas in the cerebral and cerebellar hemispheres is needed to
48
49 sustain this modality of working memory.

Figure captions

Figure 1

Event timing of a single trial of the Sternberg working memory tasks. Stimuli presented during high-load and low-load condition of (a) verbal working memory and (b) visual working memory tasks. (c) Timing of one cycle of high-load and low-load trials interleaved by a 1.6 s rest interval.

Figure 2

For display purposes, activation maps superimposed on the canonical T1-weighted rendered brain were thresholded at $T = 4.7$ [$P < 0.05$ (FWE corrected) at cluster-level]. (a) During verbal working memory, left hemispheric dominance was observed in frontal, parietal, occipital, and occipitotemporal regions. (b) During visual working memory, bilateral activations of the same brain regions were observed. The colour bar refers to activation intensity expressed in T values. Lighter colour represents increased activation intensity.

Figure 3

Coronal section views of cerebellar activations during the working memory tasks. For display purposes, activation maps were thresholded at $T = 4.7$ [$P < 0.05$ (FWE corrected) at cluster-level]. (a) During verbal working memory, bilateral superior cerebellar activations were obtained from slices $y = -78$ to $y = 57$. In the same y slices, inferior cerebellar activations were obtained only in the right hemisphere. (b) During visual working memory, bilateral superior cerebellar activations were obtained from slices $y = -80$ to $y = -57$. Bilateral inferior cerebellar activations were obtained from slices $y = -78$ to $y = -61$. The colour bar refers to activation intensity expressed in T values. Lighter colour represents increased activation intensity.

Hippocampus_L	202	5.38	-27	-36	-4
Angular_R	214	5.27	33	-58	46

Activation maxima are reported using a single subject MNI template brain (Tzourio-Mazoyer et al., 2002), $P < 0.05$ (FWE corrected) at cluster-level. Abbreviations: Inf = inferior; L = Left; Mid = middle; N_{vox} = number of voxels in a contiguous cluster; Oper = opercularis; R = right; Sup = superior; Supp = supplementary.

Table 2

		MNI Coordinates (mm)			
Brain structures	N_{vox}	SPM{Z}	X	Y	Z
Visual working memory					
Fusiform_L	17637	7.61	-33	-52	-22
Occipital_Mid_L		7.45	-25	-88	10
Fusiform_R		7.38	37	-46	-22
Supp_Motor_Area_L	1482	7.48	-1	16	46
Cingulum_Mid_R		6.75	9	24	32
Insula_R	464	6.87	37	22	-6
Precentral_L	1699	6.32	-45	6	32
Precentral_L		6.21	-35	-4	62
Precentral_L		5.59	-31	-6	54
Insular_L	171	5.59	-33	18	-4
Frontal_Inf_Oper_R	781	5.59	53	16	38
Frontal_Inf_Oper_R		5.37	49	10	28
Frontal_Inf_Tri_R		5.33	53	38	24
Hippocampus_L	43	5.45	-27	-36	2
Frontal_Mid_R	417	5.39	37	2	64
Precentral_R		5.36	33	-2	50
Parietal_Sup_R	135	5.34	11	-78	50
Thalamus_R	32	5.28	23	-30	-2

Activation maxima are reported using a single subject MNI template brain (Tzourio-Mazoyer et al., 2002), $P < 0.05$ (FWE corrected) at cluster-level. Abbreviations: Inf = inferior; L = Left; Mid = middle; N_{vox} = number of voxels in a contiguous cluster; Oper = opercularis; R = right; Sup = superior; Supp = supplementary; Tri = triangularis.

Table 3

Cerebellar brain regions activated during the working memory tasks, high-load > low-load

Brain structures	Lobule	N_{vox}	SPM{Z}	MNI Coordinates (mm)			
				X	Y	Z	
Verbal working memory							
Superior posterior cerebellum	VI	961	R	Inf	21	-63	-26
Superior posterior cerebellum	VI		R	6.87	11	-73	-23
Inferior posterior cerebellum	VII B/VIII		R	6.44	25	-70	-51
Visual working memory							
Superior posterior cerebellum	VI	930	L	7.13	-35	-59	-23
Superior posterior cerebellum	VI		R	7.12	28	-70	-19
Anterior cerebellum / Vermis	IX		-	6.75	0	-56	-33
Inferior posterior cerebellum	VII B	22	L	5.70	-25	-73	-51
Inferior posterior cerebellum	VII B	9	R	4.65	25	-73	-51

Activation maxima are reported using the probabilistic cerebellar atlas (Diedrichsen et al., 2009), $P < 0.05$ (FWE corrected) at cluster-level. Abbreviations: L = left; N_{vox} = number of voxels in a contiguous cluster; R = right.

Table 4

Means and standard deviations (SDs) of the laterality indices

ROIs	VERWM			VISWM		
	Mean	SD	Laterality	Mean	SD	Laterality
IFG	0.32	0.17	Left	0.02	0.23	Bilateral
IPL	0.59	0.20	Left	-	-	-
ITG	-	-	-	-0.04	0.26	Bilateral
CL VI	-0.37	0.40	Right	0.06	0.36	Bilateral
CL Crus I	-0.12	0.46	Bilateral	0.08	0.39	Bilateral
CL VIIB	-0.58	0.45	Right	0.05	0.51	Bilateral
CL VIIIA	-0.31	0.41	Right	0.12	0.45	Bilateral

Abbreviations: IFG = inferior frontal gyrus, IPL = inferior parietal lobule, ITG = inferior temporal gyrus, CL = cerebellar lobule, ROI = region of interest, VERWM = verbal working memory, VISWM = visual working memory.
