Abstract: Recently, all-inorganic cesium lead halide perovskite nanocrystals (IPNCs) (CsPbX_3 , $\text{X} = \text{Cl, Br, I}$) were discovered to possess superior optical gain properties appealing for solution-processed cost-effective lasers. Yet, the potential of such materials has not been exploited for practical laser devices, rendering the prospect as laser media elusive. Herein, we realized for the first time the challenging but practically desirable vertical cavity surface emitting lasers (VCSELs) based on the CsPbX_3 IPNCs, featuring low threshold ($9 \mu\text{J}/\text{cm}^2$), unidirectional output (beam divergence of $\sim 3.6^\circ$) and favorable stability. The lasing wavelength can be tuned across red, green and blue region maintaining comparable thresholds, which is promising in developing single source-pumped full-color visible lasers. It is fully demonstrated that the characteristics of the

VCSELs can be versatilely engineered by independent adjustment of the cavity and solution processable nanocrystals. Our results represent a significant leap towards practical laser sources leveraging on the advantageous CsPbX₃ IPNCs.

Solution-processed gain materials are being pursued with the promise to revolutionize the vacuum-based epitaxial semiconductor lasers aiming at developing low-cost yet high-performance laser source¹. Colloidal quantum dot (CQD) has been recognized as the ideal candidate due to the tunable emission color, enhanced optical properties and facile solution processibility²⁻⁴. Ever since the first demonstration of stimulated emission from metal-chalcogenide CQDs in 2000², significant progress has been made in improving the lasing performance^{5, 6}. However, the relatively low absorption cross-section and the high optical loss due to carrier trapping and Auger recombination (AR) still hinder the advance of CQD-lasers, especially in the short visible spectral range of blue and green^{7, 8}.

In the past years, the organic-inorganic halide perovskites, which have demonstrated impressive photovoltaic performance^{9, 10}, were also discovered to be potential optical gain media^{11, 12}. However, the commercial aspirations may be stifled by the inherent instability of these hybrid perovskites^{11, 12}. More recently, the newly engineered all-inorganic cesium lead halide (CsPbX_3 (X=Cl, Br and I)) perovskite nanocrystals are resurging as a superior optical gain material because of the large optical absorption cross-section, large exciton binding energy, high photoluminescence (PL) quantum yield and relatively low AR loss^{13, 14}. Importantly, these all-inorganic perovskite nanocrystals (IPNCs) show much enhanced endurance to ambient environment than the organic-inorganic analogues^{13, 15, 16}. Compared to traditional metal-chalcogenide CQDs, these CsPbX_3 IPNCs feature in narrow emission spectra, simple fabrication process, ease of color tunability by anion exchange, superior optical gain properties and so on¹⁷⁻²⁰. As a result, these new emerging CsPbX_3 IPNCs can be envisioned as the promising solution towards inexpensive laser sources in the future.

So far, lasers based on single CsPbX_3 nanowire have been reported^{21, 22}. Regarding lasers made from the ensemble of inorganic perovskite nanocrystals, only whispering gallery mode and random lasers which are among the easiest configurations for lasers have been demonstrated as a proof of concept^{13, 14}. However, both of these laser types lack directionality, one of the most important advantages of a laser. Moreover, all of the above lasing demonstrations fall in multi-mode operation^{13, 14}. In laser physics and applications, obtaining single-mode lasing is crucial since multi-mode operation will deteriorate the color purity and temporal stability by mode oscillation^{23, 24}. Due to the typical large cavity length to provide sufficient gain for lasing action and the relatively broad gain bandwidth of traditional lasing materials, achieving single-mode lasing is still challenging^{23, 24} and remains unaccomplished for CsPbX_3 IPNCs.

Vertical cavity surface emitting laser (VCSEL) is an important and much desired laser type which finds a broad range of applications like optical communication, high density optical storage, laser display, parallel optical computing and signal processing because of its ability to form 2-dimensional arrays, surface normal emission characteristics and high beam quality output ensuring easy coupling into an optical fibre^{25,26}. For any given gain materials, VCSELs represent the most tough laser configuration determined by the stringent criteria between gain and loss^{6,25}. As such, most surface normal devices were previously developed from complicated epitaxial growth of semiconductor heterostructures of many layers in which both bandgap alignment and lattice mismatch are big concerns²⁷⁻³⁰. The unavailability of independently adjusting the cavity and the active gain materials in an epitaxy based VCSEL makes material selection a constraint and the device cost ineffective. Thus, alternative fabrication of VCSELs with simplified processing is very appealing. Herein, we realized for the first time the high-performance VCSELs from solution-processed CsPbX₃ IPNCs. A clear evolution from spontaneous emission to lasing in the device upon optical pumping was manifested by the spectral narrowing, nonlinear increase of the PL intensity, drastic reduction of PL lifetime and remarkable decrease of output beam divergence. Both multi-mode and single-mode lasing operation have been achieved by tuning the cavity length. Thanks to the superior optical gain properties of the CsPbBr₃ IPNCs and the good match between the gain profile and the high reflectivity band of the distributed Bragg reflectors (DBRs), the lasing threshold of the IPNC-VCSELs is so low that quasi-continuous wave (q-CW) pumping is feasible. In contrast to traditional metal-chalcogenide CQD based lasers, where the thresholds for the green and blue are typically much higher than that of the red⁶, these CsPbX₃ IPNC-VCSELs lase with comparable thresholds across the whole visible spectral range, which is promising in achieving single source-pumped full-color lasers. Our results highlight the resurging CsPbX₃ IPNCs in developing the challenging but practical lasers and shed light on the feasibility of independent adjustment of cavity and gain materials for the IPNC-VCSELs, which represent a great progress towards advanced laser sources based on the advantageous CsPbX₃ IPNCs.

Results

Modification of spontaneous emission from CsPbBr₃ IPNCs by microcavity effect. The CsPbX₃ IPNCs adopted here were synthesized following the method reported by Protesescu et al.¹⁷ with slight adjustment¹³. The absorption and emission spectra of the CsPbBr₃ IPNCs are shown in Supplementary Fig. 1b, revealing the emission peak of ~504 nm with a narrow full-width at half maximum (FWHM) of ~21 nm. The corresponding transmission electron microscope (TEM) image (Supplementary Fig. 1a) displays the cubic shape with an edge length

of ~ 9 nm. To build the vertical microcavity, the commercially available dielectric DBRs consisted of 25 pairs of $\text{SiO}_2/\text{TiO}_2$ quarter-wave layers were employed as the high-reflective mirrors. Figure 1a displays the reflection spectrum of a DBR used here, which exhibits a stop-band from 430 nm to 570 nm, matching the PL spectrum of CsPbBr_3 IPNCs (see broadband reflection spectrum in Supplementary Fig. 2). The reflectivity was determined to be as high as 99.6% at ~ 500 nm. To sandwich the CsPbBr_3 IPNCs between two DBRs so as to form the prototypical VCSEL, the highly concentrated CsPbBr_3 IPNCs solution was spin-coated onto the top surface of a DBR, then, another DBR was brought upside-down in contact to the CsPbBr_3 IPNC film and finally fixed with glue. The schematic diagram (Fig. 1b), photograph (Supplementary Fig. 3) and the corresponding reflection spectrum ((Supplementary Fig. 2) of the final device are presented. Prior to the lasing investigation, the modification of spontaneous emission from CsPbX_3 IPNCs by the optical microcavity was interrogated, which could reflect the quality of the complete DBR resonator. Figure 1a shows the typical PL spectrum from the CsPbBr_3 IPNCs inserted within the cavity collected at 0° with respect to the surface normal (see Methods for details). In contrast to the PL spectrum from CsPbX_3 IPNCs spin-coated on a single DBR substrate, the PL within the cavity manifests multiple interference peaks, visualizing the presence of Fabry-Perot cavity effect. It is worth to note that the spiked emission is not laser but spontaneous emission modified by interference effect, which is further demonstrated by the following lifetime measurements (Fig. 2c). The resonant peaks can be assigned to mode numbers indexed as 29-33 based on the equation³¹: $m\lambda = 2nL$, where m is the mode number, λ is the emission wavelength, n is the refractive index of the CsPbX_3 IPNC film, L is the effective cavity length. L is estimated to be $4\text{ }\mu\text{m}$ assuming $n=2^{13}$. By changing the thickness of the CsPbBr_3 IPNC film, the optical modes of the cavity and thus the PL spectrum can be tuned as exemplified in Supplementary Fig. 4. The slight red-shift of the envelop of the emission comb relative to the free-space emission spectrum can be attributed to the reabsorption effect due to the multipass of the radiation inside the cavity²⁴. Furthermore, the spatial distribution of the radiation and the angle (θ) dependent PL spectrum from the device were examined by angle-resolved PL measurement (see Methods for details). It is found that the optical mode wavelengths gradually shift to blue as the detection angle increases (Fig. 2a), which quantitatively follows the equation: $m\lambda = 2nL\sqrt{n^2 - \sin^2\theta}$ (Supplementary Fig. 5). Such behavior states nothing but that the radiation propagation angle inside the cavity and the detection angle are correlated by Snell's law (see detailed deviations in Supporting Information)^{1,31}, further confirming that the discrete peaks originate from the Fabry-Perot interference. Notably, the radiation from the microcavity is much narrowed in space with respect to that from free-space CsPbBr_3 IPNCs (Fig. 2b), indicating that

spatially confined emission is obtained by the microcavity effect, which may shed light on developing CsPbX₃ IPNC-based light emitting diodes with directional radiation. Finally, the carrier dynamics of CsPbBr₃ IPNCs within/without microcavity was inspected by a streak camera system (Fig. 2c) (see the corresponding spectrograms in Supplementary Fig. 6). It is found that the PL decay curve within microcavity is almost identical to that in free space. A reduction of PL lifetime due to Purcell effect is not observed which can be attributed to the long cavity length and that the cavity mode only confined in one dimension³².

Vertical cavity surface emitting lasers from CsPbBr₃ IPNCs. The stimulated emission from the close-packed thin film of the CsPbBr₃ IPNCs was first studied by stripe pumping configuration^{13, 33} to exam the optical gain. As increasing the pumping density, the development of stimulated emission revealed by a much narrowed emission peak (FWHM: ~6.5 nm) can readily occur from our sample with a threshold of ~18 $\mu\text{J}/\text{cm}^2$ (Supplementary Fig. 7). Such a low-threshold optical gain from CsPbBr₃ IPNCs in combination with the favorable coupling between the emission and the cavity modes motivates us to pursue CsPbBr₃ IPNC-based VCESLs. In doing so, the pump laser beam (400 nm, 100 fs) was focused by a circular lens (focus length: 5 cm) onto the device vertically, and the PL signal was collected from the surface normal of the cavity. A 30% reflection by the DBR for pump wavelength was extracted and counted in determining the final pump intensity. Figure 3a displays the evolution of PL spectra from the device as a function of pump intensity. Under relatively low pump intensities ($< 11 \mu\text{J}/\text{cm}^2$), the PL spectra are dictated by spontaneous emission shaped by the cavity mode. With the increase of pump intensity, one of the discrete peaks with wavelength close to the stimulated emission spectra grows much faster than the others, which is accompanied by dramatic narrowing of the line-width down to ~0.6 nm. Figures 3b and c depict the change of PL intensity and the FWHM of the peaks corresponding to mode numbers from 29 to 33, respectively. The abrupt increase of the PL intensity and sudden decrease of the line-width of a particular peak indicate the achievement of lasing action^{1, 34, 35}. The lasing threshold (P_{th}) is derived to be as low as $11 \mu\text{J}/\text{cm}^2$, which is much lower than that of the CdSe/CdZnS CQDs ($65 \mu\text{J}/\text{cm}^2$), under similar conditions⁶. Importantly, due to the much larger free spectral range (FSR) of ~16 nm determined by the short cavity length than the stimulated emission line-width (6.5 nm), single-mode lasing operation was achieved. It should be noted that although the lasing peak locates at the blue side of the emission comb, it is actually on the red side of the spontaneous emission maximum of CsPbBr₃ IPNCs (Supplementary Fig. 8), in agreement with that the optical transition of the laser originates from the biexciton recombination^{13, 36, 37}.

To further verify the development of lasing, the PL dynamics as a function of pump intensity was investigated. Under pump intensity ($0.1 P_{th}$) of much lower than the threshold, the PL decay resembles the spontaneous emission trace. With the increase of pump intensity ($0.8 P_{th}$) approaching the threshold, a much faster decay channel, corresponding to the Auger recombination, appears. As the pump intensity ($1.3 P_{th}$) surpasses the threshold, the PL decay suddenly collapses to <50 ps, limited by the temporal resolution of the streak camera system, indicating the onset of lasing action³⁸.

Coherence and directionality are two basic features of a laser but are rarely examined in CQDs based lasers. Herein the directionality of the output radiation above and below the threshold is assessed by a CCD camera located 15 mm away from the laser device (inset in Fig. 3a) as well as angle-resolved PL measurement (Supplementary Fig. 9). We can see that when the pump intensity ($1.3 P_{th}$) exceeds the threshold, the divergence of the output signal remarkably decreases from 15° for spontaneous emission below P_{th} to 3.6° , thus a directional emission was obtained in our IPNC-VCSEL. Moreover, a clear interference pattern (Supplementary Fig. 10a) can be observed by using the conventional Michelson interference experiment^{39,40}. From the plot of the visibility ($V = \frac{I_{max}-I_{min}}{I_{max}+I_{min}}$, where I_{max} and I_{min} represent the intensities at the fringe maxima and minimum) as a function of detuning time or optical path difference^{39,40}, the coherence time (τ) of ~ 1 ps can be derived (Supplementary Fig. 10c).

Finally, we test the stability of the device by monitoring the lasing peak intensity versus time at pump intensity of $1.5 P_{th}$ (pulse-width: 100 fs; repetition rate: 1KHz) (Supplementary Fig. 11). Thanks to the robustness of the CsPbBr₃ IPNCs, the output signal can maintain 80% of its initial value for more than one hour, which far excels the CdSe/CdZnS CQD-lasers⁶.

Inspired by the excellent laser performance under femtosecond laser pump, it is highly promising to explore our IPNC-VCSEL pumped in the q-CW regime by a compact nanosecond laser^{7,41}, which would be more practical and cost-effective. A ns laser pump is called the q-CW just because the pump duration is much longer than that of the effective gain (~ 35 ps)⁴². Figure 4a shows the pump intensity dependent PL spectra pumped by a Q-switched nanosecond laser (pulse-width: 5 ns; repetition rate: 20 Hz; wavelength: 400 nm). The onset of lasing action is unambiguously evidenced by the spectral narrowing and nonlinear increase of the PL intensity with respect to the pump intensity (inset in Fig. 4a) with a low threshold of $900 \mu\text{J}/\text{cm}^2$. To the best of our knowledge, this is the first demonstration of CQD-VCSEL operating in q-CW regime, which represents a significant step towards continuous wave and electrical pumping. The lasing

stability under nanosecond pumping is also examined (Supplementary Fig. 11). It is found that the lasing can last over one hour with losing only 50% of initial peak intensity. The faster decrease of the lasing intensity compared to that under femtosecond pump suggests the more serious thermal issue for long pump pulse duration³⁶. So the effective thermal management (heat roll-off) shall be one of the major issues to address for future work toward stable CW operation^{36, 43}.

Furthermore, we demonstrate that multi-mode lasing operation can be produced in our IPNC-VCSELs via tuning the *FSR* to be smaller than the stimulated emission bandwidth which is enabled by increasing the effective cavity length (*L*) or film thickness of CsPbBr₃ IPNCs. Figure 4b illustrates the typical double mode lasing from the IPNC-VCSEL with *FSR* of ~6.2 nm and *L* of ~10.3 μm. Due to the longer cavity path and thus the larger round-trip gain, the lasing threshold further reduces to ~9.0 μJ/cm² (inset in Fig. 4b).

Full-color VCSELs from CsPbX₃ IPNCs with comparable thresholds. For traditional metal-chalcogenide CQDs, the lasing wavelength is generally tuned by changing the dot size because of the band gap limit^{2, 6}. For example, smaller dot size is necessitated to obtain green and blue lasers than that for red ones⁶. However, the optical loss including nonradiative AR and carrier trapping becomes more serious and the absorption cross-section reduces as the dot decreases, making the CQDs lase in short visible region challenging^{2, 8}. Despite that lasing has been demonstrated from CQDs across the full visible range⁶, the pump thresholds differ dramatically for red, green and blue colors, which hinders the realization of integrated full-color lasers with single pumping source⁴⁴. In contrast, the emission color of CsPbX₃ IPNCs can be facily tailored by composition control^{17, 18}. By inserting the blue-emitting CsPb(Br/Cl)₃ IPNCs and red-emitting CsPb(I/Br)₃ IPNCs into the DBR resonators (for the red-emitting CsPb(I/Br)₃ IPNC-VCSEL, the DBR with stop-band centered at 590 nm was employed (Supplementary Fig. 12)), we successfully achieved IPNC-VCSELs across the full visible region (Fig. 5) (see full-range spectra in Supplementary Fig. 13 and Supplementary Fig. 14 for blue and red VCSELs, respectively). Notably, the lasing thresholds for the red (19.0 μJ/cm²) and blue (25.5 μJ/cm²) are comparable to that of the green, which indicates our CsPbX₃ IPNC-VCSELs may hold great promise for developing the single source-pumped full-color visible and white lasers.

Discussion

We for the first time realized the tough yet practically desirable VCSELs based on the emerging solution-processable CsPbX₃ IPNCs. The CsPbX₃ IPNC-VCSELs operate at a very low threshold,

so that the q-CW pumping is made feasible. Such a low lasing threshold can be mainly attributed to the large absorption cross-section of the CsPbX₃ IPNCs, high PL quantum yield, relatively low Auger loss and the good match between the gain profile and the stop-band of the DBRs^{13, 14}. Especially, the absorption cross-section of the CsPbX₃ IPNCs was disclosed to be orders of magnitude higher than those of the metal-chalcogenide CQDs^{13, 14, 42}, which allows for the generation of excitons with denser concentration under the same pump density. Therefore, even though the CsPbX₃ IPNC-VCSELs stem from the biexciton recombination^{13, 37}, the pump thresholds for lasing still remain several times lower than that of the CdSe/CdZnS CQDs under similar conditions which was claimed to lase in single exciton regime⁶. Another advantage of the CsPbBr₃ IPNCs may be its cubic crystal shape. In general, dense packing of the nanocrystals in the ensemble film is essential for high effective gain and thus a low lasing threshold. In this regard, the cubic shape of CsPbBr₃ IPNCs is advantageous over the spherical ones of II-VI group metal-chalcogenide CQDs. The directionality and coherence from the laser device was clearly revealed. Taking advantage of the short cavity length and the narrow gain spectrum (~6.5 nm), single-mode lasing was achieved, attractive for various application fields. Noticeably, it is facile to independently choose the cavity characteristics and CsPbX₃ IPNCs for optimal match so that red, green and blue VCSELs can be realized with comparable pump thresholds, which is extremely difficult for epitaxial semiconductors and traditional metal-chalcogenide CQDs. We envisage that further optimization of the CsPbX₃ IPNCs, such as engineering the core/alloyed-shell heterostructure to mitigate the Auger and trapping loss⁴⁵, as well as adoption of proper thermal management in the device³⁶ could further reduce the lasing threshold and may eventually enable the continuous wave operation in the future.

Methods

Synthesis of CsPbX₃ IPNCs. Cs₂CO₃ (0.8 g), OA (oleic acid, 2.5 mL) and of ODE (octadecene, 30 mL) were mixed and kept in an argon atmosphere. The mixture was heated up to 130 °C for one hour. After that, the mixture was further heated up to 150 °C for reaction and lasted for 0.5 hour. Then, the solution was cooled down to room temperature. On the other side, 10 mL ODE, 1 mL OA and 0.36 mmol of PbX₂ (X=Cl, Br and I) were put together and kept in an argon atmosphere for one hour at temperature of 130 °C. Then, the solution was further heated up to 160 °C for reaction for 10 minutes. Finally, the Cs-precursor (1 mL) was quickly added into the

solution and cooled down by ice. More information about the synthesis of CsPbX₃ IPNCs can be found in reference 13.

Optical characterization. To investigate the modification of spontaneous emission from CsPbX₃ IPNCs by microcavity effect, the same femtosecond laser source (excitation wavelength: 400 nm, pulse-width: 100 fs, repetition rate: 1000 Hz) was employed as that used in the following lasing studies to maintain consistency. The excitation intensity was kept very low (0.5 μJ/cm²), far less than the threshold. We also have tried the continuous wave He-Cd laser as the excitation source, where similar spiked emission was observed, further confirming the spiked emission is not laser. The angle dependent PL signal was recorded as a function of detection direction by a home-built fiber-optics system. In particular, the collection fiber with diameter of 200 μm was attached to a 50 mm diameter rotating stage with the sample mounted at its center. The distance between the fiber and the sample is set as 15 mm. The other side of the fiber was coupled to a 320 mm monochromator combined with a charge coupled device detector. For the lasing investigation, the laser beam with wavelength of 400 nm generated by second harmonic generation from the seed with wavelength of 800 nm was focused by a circular lens (focus length: 5 cm) onto the VCSEL vertically, and the spot diameter on the sample was ~90 μm. The output signal was collected from the other side of the VCSEL by the above-mentioned fiber-optics system.

Acknowledgements

This research is supported by the Singapore National Research Foundation through the Competitive Research Programme (CRP) under Project No. NRFCRP6-2010-02, the Singapore Ministry of Education through the Academic Research Fund under Projects Tier 1- RG92/15 and MOE 2011-T3-1-005 (Tier 3), and National Basic Research Program of China (grant number 2014CB931700).

Author contribution

All authors contributed extensively to this work. Y.W. and V.N. conducted spectroscopic experiment and analysis. Y.W. and H.S. conceived and fabricated the VCSEL structure. X.L. and H.Z. synthesized the IPNC samples. H.S. and H.Z. supervised the project. Y.W., X.L., V.N., H.Z., and H.S. analyzed data and interpreted the results, and wrote the manuscript with input from all authors.
