There is growing interest in copper (Cu) wire bonding due to its significant cost savings over gold wire. However, concerns on corrosion susceptibility and package reliability have driven the industry to develop alternative materials. Recently, palladium-coated copper (PdCu) wire has become widely used as it is believed to improve reliability. In this paper, we experimented with 0.6 mil PdCu and bare Cu wires. Palladium distribution and grain structure of the PdCu Free Air Ball (FAB) were investigated. It was observed that Electronic Flame Off (EFO) current and the cover gas type have a significant effect on palladium distribution. The Free Air Ball (FAB) hardness was measured and correlated to palladium distribution and grain structure. First bond process responses were characterized. The impact of palladium on wire bondability and wire bond intermetallic using a high temperature storage test was studied. These results for PdCu wire were compared with bare Cu wire.

Introduction

Fine copper and palladium-coated copper wires have been widely used in the electronic industry in recent years (1). As electronic components continue to shrink and advanced devices require high pin counts, 0.6 mil fine palladium-coated copper wire is actively being qualified before being introduced into manufacturing production lines to accommodate such technological developments (2). Assembly and Packaging companies worldwide are known to use different wires from different manufacturers of their choice, therefore there is a need to determine optimized FAB and bonded ball parameters for each wire type to maximize the wire bonding capabilities. In addition, with the recent advancements in copper wire technology, the cost factor, and the implication of a Pd coating to the process response, there is a resurgence of interest from customers to run bare Cu despite the advent of PdCu wire. PdCu wire has been shown to have enhanced reliability under humid and electrically biased test conditions (3-5). Currently, most wire manufacturers are still debating how EFO conditions affect the Pd distribution in the FAB and bonded ball. The effect of Pd distribution on wire bondability and package reliability is not well understood. In this paper, we look at such ultra-fine pitch processes using 0.6 mil PdCu and bare Cu wires from a variety of wire manufacturers with the aim of determining example optimized process parameters on a K&S Iconn ProCu Ball Bonder through a series of systematic FAB and bonded ball experiments. By varying

EFO parameters, we were able to observe how FAB repeatability and ball shape responses vary to different extents. Next, typical first bond response in the form of measuring ball size, ball height, ball shear, aluminum pad splash, and wire pull were compared with bare copper wire.

All these bonding experiments were married with advanced material analysis to correlate the bonding responses to the material properties of the wire bonds. Palladium distribution and grain structure of the cross-sectioned FABs were studied and analyzed. These were correlated to the bonded ball hardness. Intermetallic formation and growth under unmolded high temperature storage (HTS) was also analyzed. The different wire properties, bonding responses, and material analysis results were presented at the end with conclusions on their correlations and implications on device performance.

Experimental

All FAB and bonded ball testing was performed on a Kulicke and Soffa (K&S) Iconn ProCu automatic ball bonder using 0.6 mil PdCu and bare Cu wires. A K&S Cupra3G capillary was used for bonding, with a hole diameter of 18 μm , a chamfer diameter of 22 μm and a tip diameter of 50 μm . The wire bonding was run using two types of cover gas (forming gas and nitrogen) for PdCu wire and only forming gas for bare Cu wire. The forming gas is a gas mixture consisting of 95% nitrogen and 5% hydrogen. The flow rate of forming gas or nitrogen was set to 0.5L/min. The FAB in this study was prepared using the “Formed FAB” process and the FAB diameter was verified using the Nexiv microscope to ensure a ball size ratio (BSR) of 1.6 and a FAB diameter of 24 μm . Ball size ratio is defined as the FAB diameter divided by the wire diameter.

Selected FAB samples were cross sectioned using a FEI Dual-Beam Focused Ion Beam (FIB) system and the grain structure was analyzed using an EDAX Digiview IV Electron Backscattered Diffraction (EBSD) detector. EDAX Orientation Imaging Microscopy (OIM) analysis software was used for grain size and grain orientation analysis. Pd distribution found within the FAB and bonded ball was analyzed using a JEOL JSM-6610 LV Scanning Electron Microscope (SEM) equipped with an Oxford Instrument Inca Energy Dispersive X-Ray (EDX) program. Pd concentration in the FAB bulk was analyzed using JEOL JXA 8530F Field Emission Electron Probe Micro Analyzer Wavelength dispersive X-ray (EPMA-WDX).

Thermosonic ball bonding was performed on aluminum pad die-attached on a BGA substrate, using an optimized set of process parameters involving contact velocity (CV), ultrasonic current (USG) and bond force to ensure a bonded ball size of 27 μm and ball height of 7 μm . Process responses such as ball diameter, ball height, ball shear, first bond pull and aluminum pad splash in the USG vibration direction were measured.

Results and Discussion

a. FAB Repeatability for PdCu and Bare Cu wires

In this study, we compared PdCu FABs from two different wire manufacturers. We looked at a few wire types provided by the manufacturers. The Pd content for Type 1 and Type 2 wires provided by Manufacturer A was specified to be 2.8 wt%. The Pd content for Type 1 and Type 2 wires provided by Manufacturer B was specified to be 2.1 wt% and 1.6 wt%, respectively. Forming gas was used to form the FABs unless otherwise stated. EFO firing time was adjusted accordingly to ensure the same ball size ratio of 1.6 for each EFO current setting. FAB repeatability was tested, which is a measure of the ability to form consistently sized FABs. Figure 1 illustrates that FAB repeatability generally improves with increasing EFO current, as shown by the decreasing standard deviation at higher EFO currents. The tendency for FAB repeatability to improve with increasing EFO current is a result of more stable plasma at high EFO current. In addition, at higher current, the fire time is shorter, so external influences have a reduced potential to affect the FAB formation process. Conversely, at a lower current and longer fire time, more heat is lost to conduction into the wire causing more variations. Figure 1 also shows that FAB repeatability is similar for PdCu and bare Cu wires and the relative standard deviation for all the wire types generally meets the specification of 1% of the FAB diameter. Relative standard deviation is defined as the standard deviation divided by the average FAB diameter. In these experiments, the Pd coating thickness did not have a strong influence on FAB repeatability. Manufacturer B Type 4 FAB shows the best repeatability which might be due to the dopants added to the copper core.

Next, we looked at the effect of cover gas type on FAB repeatability. As shown in Figure 1, FABs formed in nitrogen exhibited degraded repeatability compared to forming gas. This could be due to a higher degree of malformed FABs in nitrogen. We can conclude that FAB repeatability is affected by EFO current and cover gas type.

Figure 1. FAB repeatability for PdCu and bare Cu wires for a range of EFO currents

b. Palladium Distribution in the FAB

The effect of Pd on reliability has been an increasingly debated topic of discussion and there is a need to better understand the effect of Pd distribution on package reliability. Manufacturer A Type 2 wire was selected for the rest of the material analysis tests. PdCu and bare Cu FABs were bonded at three different EFO current settings (low, mid and

high) with different cover gas types (forming gas vs nitrogen). The FABs were then cross-sectioned to reveal the palladium distribution in the FAB. Optical images were taken using bright field imaging techniques and Pd rich regions were analyzed. SEM-EDX elemental mapping was then used to verify the grey regions to be Pd rich regions. The optical and EDX analysis results are shown in Figure 2.

Some malformed balls (Apple bites) were observed for FABs formed at a low EFO current setting in forming gas, as shown in Figure 3. The degree of malformation is worse for FABs bonded in nitrogen compared to forming gas. This can account for the higher relative standard deviation in FAB diameter when using nitrogen. The apple bite effect can be explained, at least in part, by the different heating effect of forming gas and nitrogen (3). For bare Cu wire, no malformed balls were observed at both low and high EFO currents. It is to be noted here that this particular PdCu wire tested is a prototype wire and similar test conditions were repeated with the latest wire by the wire supplier, no malformed balls was observed at the low EFO current and in nitrogen.

With forming gas and a low EFO current setting, a thin uniform ring of Pd-rich phase was observed around the FAB periphery, with Pd found at the FAB tip. A higher EFO current produces a steeper temperature gradient, causing Cu to flow out at a faster rate. Hence, at a mid EFO current setting, the Pd-rich phase mostly concentrates at the neck region of the FAB. At an even higher EFO current, the Pd-rich phase is mostly at the periphery neck, with some infusion of Pd into the FAB bulk. This is due to the turbulent flow of Cu and partial melting of Pd, causing random distribution of Pd in the FAB bulk. With nitrogen gas and a mid EFO current setting, a Pd-rich layer was seen around the peripheral, with Pd found near the tip. It was observed that Pd and Cu do not form a homogeneous solid solution at all EFO currents settings, resulting in Pd rich areas. The heat energy generated by the EFO spark might not be sufficient to allow Pd to melt completely since it has a higher melting point compared to Cu. The Pd rich regions detected by EDX elemental maps were observed to correlate well with the grey regions in the optical images. From these analytical techniques, it can be concluded that EFO current has a strong influence on Pd distribution in the FAB.

Figure 3. Example of an apple bite FAB observed at low EFO Current in Forming Gas

c. Grain Structure Analysis along the FAB

Apart from determining palladium distribution in the FAB, the grain structure of the FAB was analyzed. FABs were cross sectioned along the wire direction using dual-beam FIB and the grain structure was analyzed *in-situ* using EBSD detector attached to the FIB system. This polishing technique using a dual-beam FIB allows a fine surface finish ideal for obtaining diffraction patterns. Sample preparation *in-situ* and under vacuum prevents oxidation of samples which will degrade the observation. From Figure 4 and 5, it can be seen that grain growth in the FAB region is along the wire direction. This is due to the temperature gradient from the tip of the ball to the wire, produced when the wire tip is melted by the EFO spark. It can be seen that the grain is coarser at the FAB compared to the wire. As the wire is melted, the temperature at the Heat Affected Zone (HAZ) increases which leads to grain recrystallization and grain growth. In gold wire bonding, the grains at the HAZ were observed to be coarser than the virgin wire (8). However, from Figure 4, it was observed that the HAZ region cannot be easily distinguished from the virgin wire. This was also observed for bare copper wire as shown in Figure 5. This

could be due to the gradual transition in grain size going from the HAZ to the virgin wire. Also, it could be due to annealing as part of the Cu and PdCu wire manufacturing process which results in recrystallized uniaxial grains in the wire.

Figure 4. EBSD image of PdCu wire bonded at low EFO current in forming gas.

Figure 5. EBSD image of bare Cu wire bonded at low EFO current in forming gas.

d. Grain Structure Analysis across the FAB

Since the grain structure across the FAB directly impacts the ball bonding process, a cross section was performed across the FAB, with grain size and grain orientation data being collected. Figure 6 shows the grain structure for the FABs at different EFO currents and cover gas types (forming gas vs nitrogen). No preferential orientation was observed for all FABs bonded at the different settings.

Figure 6. EBSD images of PdCu and bare Cu wire across the FAB

The FAB grain size was calculated by discounting the smaller grains at the FAB periphery. An individual value plot and box plot of the grain size were obtained using Minitab statistical software as shown in Figure 7. From the individual value plot, it can be seen that there is a large variation in the individual grain size. The mean grain size value was observed to be smaller at higher EFO current, with the difference in grain size around 0.5 μm as shown in Table 1. However, since the data spread is similar as shown in the box plot, the grain size at low and high EFO currents are not considered to be significantly different. Cover gas type has no significant effect on the grain size. There is no significant difference in grain size between PdCu and bare Cu FAB as the FAB bulk is essentially copper for both PdCu and bare Cu wire.

According to the Hall-Petch Equation, the yield strength varies with the grain diameter according to the equation (6),

$$\sigma^y = \sigma_0 + k_y d^{-\frac{1}{2}} \quad [1]$$

where d is the average grain diameter

σ_0 and k_y are constants for a particular material.

For copper, $\sigma_0 = 25\text{MPa}$ and $k_y = 0.11 \text{ MPa m}^{1/2}$ (7)

A fine grained material is harder and stronger than one that is coarse grained as the former has more grain boundaries to impede dislocation motion. Based on the results, it can be deduced that the FAB hardness is not influenced by the bulk copper as the copper grain size in the FAB is similar across all settings.

Figure 7. Individual value plot and box plot of FAB grain size at different settings

TABLE 1. Mean grain size for PdCu and bare Cu FAB.

Wire Type	Gas Type	EFO current	Mean Grain Size (μm)
PdCu	Forming gas	Low	5.28
		Mid	4.65
	Nitrogen	Low	5.05
		Mid	4.56
Bare Cu	Forming gas	Low	5.26
		Mid	4.48

e. Pd composition inside the FAB bulk

EPMA-WDX point analysis was used to analyze and verify the Pd concentrations inside the FAB bulk as it provides a quantitative chemical analysis and is able to detect a trace concentration of Pd. The analysis was done on PdCu FABs formed at low and mid-level EFO currents, in forming gas and nitrogen. Figure 8 shows an EPMA image with point analysis done in the FAB bulk. The concentration of Pd in the FAB bulk is out of the detection limit of 0.036 wt% Pd. We can conclude that most of the Pd stays at the FAB periphery and does not diffuse into the FAB bulk.

Figure 8. EPMA image of PdCu FAB

f. FAB hardness

As the hardness of a FAB affects its bondability on an aluminum pad (8), a hardness test was performed on the FABs. FABs were bonded onto a test chip using the same first bond parameters and the FAB hardness was measured using an in-situ hardness measurement technique on the wire bonder. This technique gives an overall FAB

hardness sensitive to the FAB tip compared to a nano-indentation test which gives a more localized hardness measurement. FAB hardness can be affected by a few factors as illustrated by the impact diagram in Figure 9. FAB hardness results for different EFO current settings and gas types are shown in Table 2. As expected, the hardness value of PdCu FABs is higher than for bare copper FABs due to the presence of Pd which is harder than Cu. For bare Cu, the FAB hardness is not dependent on EFO current. However for PdCu, it was also observed that FAB hardness is strongly influenced by the EFO current. Low EFO current produced a slightly harder PdCu FAB compared to high EFO current. As discussed earlier, lower EFO current results in the presence of a thin Pd at the FAB tip while a higher EFO current gives Pd concentrated at the FAB neck. The presence of Pd at the FAB tip could have resulted in the increased overall hardness of the FAB. The hardness at the low EFO current setting was about 7% higher compared to the high EFO current which may not be significantly different depending on pad sensitivity.

Figure 9. Impact diagram showing factors affecting FAB hardness

TABLE 2. Hardness value for PdCu and bare Cu FABs.

Wire Type	Gas Type	EFO current	Hardness value (No unit)
PdCu	Forming gas	Low	18.42
		Mid	17.22
	Nitrogen	Low	18.36
		Mid	17.31
Bare Cu	Forming gas	Low	16.30
		Mid	16.10

g. First Bond Process

The presence of Pd at the FAB tip might form a Pd-rich layer at the bond interface affecting wire bond reliability. First bond parameters were optimized to produce the desired shear strength. EFO firing time was adjusted across the different EFO settings to obtain a bonded ball diameter of 27 μm and a bonded ball height of 7 μm . The same first

bond parameters were then applied for all of the EFO current settings. All first bond work was performed in forming gas.

Figure 10 shows the Pd distribution of the bonded balls formed with forming gas. It was observed that the low EFO current setting does not produce a visible Pd-rich layer at the interface. This might be due to the thin Pd-rich layer at the FAB periphery. A visible layer of Pd-rich region was found at the bond interface with the optimized low EFO current setting. For the mid EFO current setting, presence of Pd was found at the bond interface. For the high EFO current setting, some Pd infusion was observed in the bonded ball. It was observed that there is no systematic trend like the case of the FAB and also there is a slight variation in the concentration of Pd at the bond interface within the same setting. This could be due to the Pd coating thickness variation in the PdCu wire.

There is no significant difference in the first bond process response for the different EFO current settings as shown in Table 3. Process window in this paper is defined as the range of a bonding parameter (typically USG) that does not show lifts or peels in a pull test (11). From Figure 11, we can see that the process window is similar for mid and high EFO current settings. The optimized low EFO current improved the process window giving less ball lifts and pad peels and a bigger window which is probably because this setting gives the best FAB size consistency. It can be seen that FAB hardness and the presence of Pd at the tip does not have a significant effect on the wire bondability. The presence of Pd at the bond interface did not result in more pad peels. This can be attributed to the slight difference in FAB hardness between the low and high EFO currents.

Figure 10. EDX elemental map showing Pd distribution for bonded ball at various EFO current settings

TABLE 3. First bond Process Response for PdCu wire

Process Response	Optimized Low EFO current	Mid EFO Current	High EFO Current
Ball Diameter (μm)	27.63	27.78	28.10
Ball Height (μm)	7.29	7.08	7.06
Aluminum Splash (μm)	31.27	31.25	31.51
Shear (g)	8.96	9.00	8.71
Shear/Area (g/mil^2)	9.6	9.6	9.1
Pull Average (g)	5.59	5.74	5.73
Pull Min (g)	5.10	5.28	5.14

Figure 11. Process Window for Different EFO Current Setting in forming gas

h. High Temperature Storage

It is of interest to study how the Cu-Al interfacial reaction and morphology are affected by the presence of Pd at the bond interface. Unmolded bonded samples for the optimized low EFO current setting bonded in forming gas were subjected to High Temperature Storage (HTS) at 175 °C in an air environment up to 168 h.

Cross-sections of the bonded ball at different annealing durations were analyzed using FESEM. It was reported that nano voids were present at the bond interface of PdCu bonds formed in nitrogen (9) and no voids were found when bonded in forming gas (11). As shown in Figure 12, numerous nano voids were observed in the as-bonded state along the bond interface and at the ball neck periphery. These are the areas where there is presence of Pd and it can be seen that nano voids are strongly related to the presence of Pd. The presence of voids in the as-bonded state suggests that they could have been formed during the formation of FAB and it can be explained by volume shrinkage during the solidification of the FAB. Voids are present at the bond central and bond periphery in the as-bonded state and after annealing as shown in Figure 13.

Figure 14 shows the IMC growth and formation with annealing time. The growth rate of Cu-Al IMC is slow and exhibits island type of morphology as shown in Figure 14a after annealing for 168 h. There is no visible IMC at the interface in the as-bonded state as shown in Figure 14b. This is due to the resolution limit of FESEM and a more accurate analysis by Transmission Electron Microscope (TEM). (10) reported that ~20 nm island-like CuAl_2 IMC particles have been formed in the as-bonded state. Two layers of IMCs were formed at 24 h and 168 h annealing time, one close to the Cu bond and the other abutting the Al pad. Singh *et al.* (11) also reported two layers of IMCs, namely CuAl_2 and Cu_9Al_4 after 24 h and 168 h of annealing. The two layers of IMCs were observed to be separated in some regions at 24 h and the gap increased at 168 h. The native aluminum oxide layer could be broken down during IMC formation, forming a discontinuous layer between the IMCs.

Tests were done to determine the first bond pull value and process window after annealing at 24 h and 168 h. The results for pull strength are given in Table 4 and the process window at different annealing durations is shown in Figure 15. Although the process window shrinks drastically with annealing time with no process window found at 168 h, the pull values only decreased slightly. The increase in pad peels with annealing time can be attributed to the growth of IMC both laterally and vertically which resulted in irregular volume increase over that of the original Al metallization. The resultant stress could contribute to more pad peels over time.

Conclusion

PdCu wire has recently been widely adopted for bonding of fine pitch devices due to its longer shelf life, stitch bond robustness and enhanced reliability. This work compared the FAB formation and wire bonding process between PdCu and bare Cu wires. We noted the added challenge of malformed balls with PdCu wire which is affected by the gas type and EFO current. Pd distribution was shown to be strongly influenced by the

EFO current and cover gas type, with the EFO current being the main factor. The EFO setting was tuned to produce different Pd distribution for the study of wire bond reliability. Nano voids were observed in the as-bonded PdCu bonds and were found to be strongly related to the presence of Pd. Two layers of IMCs were observed after annealing the PdCu bond at 175 °C for 24 and 168 h. More work will be done to investigate the influence of Pd distribution and presence of nano voids to wire bond reliability.
