1 The Crystal Chemistry of $\text{Ca}_{10-y}(\text{SiO}_4)_3(\text{SO}_4)_3\text{Cl}_{2-x-2y}\text{F}_x$ Ellestadite2 Yanan Fang,^{*,†} Clemens Ritter,[‡] and Tim White^{†,§}3 [†]School of Materials Science & Engineering, Nanyang Technological University, 50 Nanyang Avenue, 639798, Singapore4 [‡]Institute Laue-Langevin, 6 rue Jules Horowitz, 38042 Grenoble Cedex 9, France5 [§]Centre for Advanced Microscopy, Sullivan's Creek Road, Australian National University, Canberra ACT 0200 Australia6 **S** Supporting Information

ABSTRACT: Fluor-chlorellestadite solid solutions $\text{Ca}_{10}(\text{SiO}_4)_3(\text{SO}_4)_3\text{Cl}_{2-x}\text{F}_x$, serving as prototype crystalline matrices for the fixation of hazardous fly ash, were synthesized and characterized by powder X-ray and neutron diffraction (PXRD and PND), transmission electron microscopy (TEM), and Fourier transform infrared spectroscopy (FTIR). The lattice parameters of the ellestadites vary linearly with composition and show the expected shrinkage of unit cell volume as fluorine (IR = 1.33 Å) displaces chlorine (IR = 1.81 Å). FTIR spectra indicate little or no OH^- in the solid solutions. All compositions conform to $P6_3/m$ symmetry where F^- is located at the $2a$ (0, 0, $1/4$) position, while Cl^- is displaced out of the $6h$ Ca(2) triangle plane and occupies $4e$ (0, 0, z) split positions with z ranging from 0.336(3) to 0.4315(3). Si/S randomly occupy the $6h$ tetrahedral site. Ellestadites rich in Cl ($x \leq 1.2$) show an overall deficiency in halogens (<2 atom per formula unit), particularly Cl as a result of CaCl_2 volatilization, with charge balance achieved by the creation of Ca vacancies ($\text{Ca}^{2+} + 2\text{Cl}^- \rightarrow \square_{\text{Ca}} + 2\square_{\text{Cl}}$) leading to the formula $\text{Ca}_{10-y}(\text{SiO}_4)_3(\text{SO}_4)_3\text{Cl}_{2-x-2y}\text{F}_x$. For F-rich compositions the vacancies are found at Ca(2), while for Cl-rich ellestadites, vacancies are at Ca(1). It is likely the loss of CaCl_2 which leads tunnel anion vacancies promotes intertunnel positional disorder, preventing the formation of a $P2_1/b$ monoclinic dimorph, analogous to that reported for $\text{Ca}_{10}(\text{PO}_4)_6\text{Cl}_2$. Trends in structure with composition were analyzed using crystal-chemical parameters, whose systematic variations served to validate the quality of the Rietveld refinements.

1. INTRODUCTION

21 Structural adaptation in apatites makes them suitable for
22 environmental remediation,¹ catalysis and energy production,²
23 as well as the traditional biomedical uses of bone and teeth
24 replacement.^{3,4} Optimization of chemically substituted apatites
25 for these applications demands a comprehensive understanding
26 of their chemical and crystallographic properties. Apatites also
27 show promise as waste form ceramics for the immobilization of
28 incinerator fly ash,⁵ however our crystallochemical knowledge is
29 presently insufficient to tailor formulations and predict
30 durability reliably.

31 Ellestadite is a silicon- and sulfur-rich member of the apatite
32 family of the general composition $\text{Ca}_{10}(\text{SiO}_4)_{3-x/2}(\text{PO}_4)_x(\text{SO}_4)_{3-x/2}(\text{F/Cl/OH})_2$,⁶ when described in $P6_3/m$
33 symmetry the unit cell contains two formula units and the
34 crystallochemical representation is $[A(1)]_4[A(2)]_6(\text{BO}_4)_6\text{X}_2$
35 ($A = \text{Ca}$, $B = \text{Si/P/S}$, and $X = \text{F/Cl/OH}$) (Figure 1a). The
36 topology is zeolite-like, in that a framework composed of
37 $\text{Ca}(1)\text{O}_6$ metaprism columns, corner-connected to $(\text{Si/P/S})\text{O}_4$
38 tetrahedra, creates tunnels perpendicular to the basal plane that
39 enclose $\text{Ca}(2)\text{O}_5(\text{F/Cl/OH})$ polyhedra. While phosphate
40 apatites are generally hexagonal, the symmetry of ellestadite
41 remains controversial. In a single crystal X-ray diffraction study
42 of a specimen from Chichibu Mine, Sudarsanan⁷ assigned the
43 space group as $P2_1/m$ that differentiated the substitutional
44 positions of SO_4 and SiO_4 for PO_4 groups. This ordering was
45 incomplete and the presence of trace elements obscured an
46 unambiguous solution. In another mineral study, Organova et
47 al.⁸ reported $P2_1$ symmetry which yields three independent (Si/
48 P/S) O_4 tetrahedral sites and two discrete CaO_6 metaprisms

(Figure 1b). Saint-Jean and Sweden⁹ synthesized chlorellestadite
50 under different conditions (annealing time, temperature, CaCl_2
51 content), but only the hexagonal phase was observed. Thus, the
52 precise arrangement of the metalloids in ellestadite and its
53 symmetry remain in question, and may be dependent on
54 petrogenesis or fabrication conditions.

55 The scope of this work was to synthesize and characterize
56 fluor-chlorellestadites, $\text{Ca}_{10}(\text{SiO}_4)_3(\text{SO}_4)_3\text{Cl}_{2-x}\text{F}_x$, as simplified
57 surrogates for apatite derived from the stabilization of certain
58 solid waste ashes, and establish the continuity of the solid
59 solution series. The role of substituted fluorine in promoting
60 higher chemical stability (e.g., reducing dental caries¹⁰) and
61 thermal resistance (e.g., higher melting points¹¹) is well-known,
62 with the interaction between fluorine and chlorine capable of
63 attenuating these properties. Commonly, the fluor- and chlo-
64 rellestadites are regarded as isostructural, although the halides
65 reside at different locations along the c -axis anion tunnels. In
66 the synthetic fluorellestadite ($P6_3/m$) endmember, F^- at (0, 0,
67 $1/4$ and 0, 0, $3/4$) lies in the center of a Ca(2) triangle on the
68 mirror planes at $z = 1/4$ and $z = 3/4$.¹² In the corresponding
69 chlorellestadite endmember, Cl^- cannot fit into the Ca(2)
70 triangle (ionic radii for $^{\text{VI}}\text{F}^- = 1.33$ Å and $^{\text{VI}}\text{Cl}^- = 1.81$ Å¹³),
71 and statistically occupies (0, 0, z) sites, ~ 1.1 Å above or below
72 the mirror plane.⁹ In the case of natural hydroxyellestadite,
73 Sudarsanan⁷ refined separate sites for OH^- (0, 0, 0.2033), F^-
74 (0, 0, $1/4$), and Cl^- (0, 0, 0.3644) in $P2_1/m$ with site
75 occupancies of 0.806(9), 0.15(6), and 0.092(5) respectively.

Received: August 3, 2011

Figure 1. (a) Hexagonal $P6_3/m$ apatite structure of $[A_4][A_6](BO_4)_6X_2$. The AO_6 metaprisms contain calcium, while the BO_4 tetrahedra accommodate phosphorus, sulfur and silicon. The tunnel contains fluorine, chlorine or oxygen without intertunnel correlation. (b) Monoclinic $P2_1$ apatite structure of $[A_4][A_6](BO_4)_6X_2$. The AO_6 metaprisms contain calcium while the BO_4 tetrahedra accommodate phosphorus, sulfur and silicon. The tunnels contain fluorine, chlorine, or oxygen where intertunnel correlation leads a doubling of the b -axis metric.

Onac et al.¹⁴ suggested minor substitutions of F^- and Cl^- at the same site as OH^- in a hydroxyllellastadite ($P6_3/m$) from Cioclovina Cave, Romania, although at the unit cell scale this is unlikely to satisfy bond valence sum criteria. In general, the interaction between F^- and Cl^- , and the influence on $Ca_{10}(SiO_4)_3(SO_4)_3X_2$ (where $X = F, Cl$) ellestadite require clarification. Two reports concerning the structural adjustments and anion tunnel accommodation in binary solid solutions of (Cl, OH) or (F, OH) in calcium phosphate apatite $Ca_{10}(PO_4)_6X_2$, and ternary solutions of $(F, Cl, OH)^{15,16}$ have appeared, but less is known about the (F, Cl) system. Mackie and Young¹⁷ studied two fluor-chlorapatite compositions with $F/(F+Cl)$ ratios of 0.17 and 0.41, and included a second fluorine site in addition to that on the mirror plane. Hughes et al.¹⁸ suggested that OH^- may be an essential component in stabilizing natural fluor-chlorapatite solid solutions. The presence of a miscibility gap in natural gem-grade apatite from Brazil has been described by Ferraris et al.,¹⁹ where atomic scale studies by high-resolution and analytical TEM revealed the phase separation of fluorine-enriched and chlorine-enriched phosphate apatite domains from ellestadite in the nanoscale. An understanding of the structural atomic arrangement and physical-chemical properties of fluor-chlorellellastadite is an essential prerequisite for formulating synthetic ellestadites for hazardous waste immobilization. To this end, infrared spectroscopy, powder X-ray and neutron diffraction, and transmission

Figure 2. Expanded views of FT-IR spectra for the fluor-chlorellellastadite solid solution. (x in $Ca_{10}(SiO_4)_3(SO_4)_3Cl_{2-x}F_x$).

electron microscopy were used here to examine the structural adaptations and nanometric properties of synthetic fluor-chlorellellastadite.

2. EXPERIMENTAL METHODS

2.1. Synthesis. $Ca_{10}(SiO_4)_3(SO_4)_3Cl_{2-x}F_x$ ($x = 0, 0.4, 0.8, 1.2, 1.6$, and 2) were synthesized by solid-state reaction. The starting materials were prepared by preheating $CaCO_3$ (Merck, p.a.) at 1000 °C for 12 h; SiO_2 (Sigma-Aldrich, 99.99%) and $CaSO_4 \cdot 2H_2O$ (Merck, p.a.) at 600 °C for 4 h; and $CaCl_2 \cdot 2H_2O$ (Riedel-de Haën, puriss.) at 400 °C for 4 h. Stoichiometric mixtures of CaO , $CaSO_4$, SiO_2 , $CaCl_2$, and CaF_2 were manually ground with acetone and calcined at 900 °C for 5 h in an alumina crucible, then reground and sintered at 950 °C for a further 9 h.

2.2. Crystallographic Characterization. Powder X-ray diffraction (PXRD) and neutron diffraction (PND) were combined for structural characterization. PXRD measurements were performed for phase identification and mass balance using a Bruker D8 high-resolution X-ray powder diffractometer (Cu-K α radiation) operated at 40 kV and 40 mA. Scans were collected from 8° to 140° with a step size of 0.01° and a dwell time per step of 1 s. All specimens were spiked with standard silicon (10 wt %, NIST660a, $a = 5.40825$ Å) to determine the unit cell constants absolutely. Powder neutron diffraction patterns were acquired at the Institute Laue-Langevin (ILL) Grenoble (France) using the high resolution D1A diffractometer with a wavelength of 1.3894 Å, a 2-theta range of 0° to 150° and scan step of 0.05° at room temperature. The diffractometer is equipped with a focusing Ge monochromator set at a takeoff angle of 123°, and 25 standard 3He counter detectors. Approximately 2 g of ellestadite was loaded into a 9 mm diameter cylindrical sample container that was rotated during acquisition.

The structure refinements were carried out by the Rietveld method using TOPAS²⁰ with a pseudo-Voigt peak shape profile and a starting model using the atomic positions of $Ca_{10}(SiO_4)_3(SO_4)_3Cl_2$ in hexagonal $P6_3/m$.²¹ Although monoclinic forms have been documented, such occurrences were not observed in this study, as 2b

Figure 3. Rietveld fitting pattern for (a) $x = 0$, (b) $x = 0.4$ and (c) $x = 2$. (x in $\text{Ca}_{10}(\text{SiO}_4)_3(\text{SO}_4)_3\text{Cl}_{2-x}\text{F}_x$) Lines and dots denote observed and calculated profile intensities, respectively. Short vertical bars represent Bragg reflection positions. The difference (observed – calculated) is plotted below.

superstructure reflections were absent, and improvements in R values with lower symmetries ($P2_1/m$; $P2_1$) were insignificant. For each data set, a five-coefficient Chebychev function and $1/x$ background, a peak shift, a zero error, unit cell parameters, and crystal size were refined sequentially with temperature displacement parameters and occupation factors of each atomic site kept constant. After several refinement cycles, the calcium positions (Ca(1) and Ca(2)) were released, followed by the silicon/sulfur and oxygen positions. The mole ratio of Si:S at the tetrahedral site was fixed at 1:1. The oxygen sites were fully tenanted, while the occupancies of calcium, chlorine and fluorine were allowed to vary. For nonstoichiometric ellestadites, the occupancy factors of Ca and Cl were constrained to maintain charge balance (see

Discussion and Table 3). Isotropic temperature displacement parameters for all atoms were refined in Ca(1)/Ca(2)/Cl/F and Si/S/O(1)/O(2)/O(3) groups to the same value. The refinement cycles were terminated when convergence was reached. Scattering lengths of 0.4700, 0.4149, 0.2847, 0.5803, 0.5654, and 0.9577×10^{-12} cm were used for Ca, Si, S, O, F, and Cl, respectively.²² Difference-Fourier maps were generated using Jana2006,²³ specifically to examine the location of anion scattering centers in the tunnels. The Ca(1)O₆ metaprism twist angle (φ) was calculated according to the method of White and Dong²⁴ for crystallochemical diagnosis, and verify trends bond angles as a function of composition. To objectively assess the reliability of the Rietveld refinements singular value decomposition as implemented in

^aR_B = $\sum_i |I_{k0} - I_{kl}| / \sum_i I_{k0}$. ^bNot refined.

SVDdiagnostic,²⁵ was used to confirm the statistical robustness of the analysis.

2.3. Infrared Spectroscopy. FTIR spectroscopy was used to study the effect of the fluorine substitution on silicate and sulfate absorption bands of ellestadite, and exclude the possible incorporation of CO₃²⁻ and OH⁻. Infrared spectra were recorded over the range 400–4000 cm⁻¹ with a Fourier Transform Infrared Spectrometer (Perkin-Elmer Spectrum 2000) using the KBr pellet technique, where ellestadite (~1 mg) was ground with oven-dried KBr (200 mg). This homogenized mixture was pressed into 10 mm diameter transparent pellets. Measurements were carried out with a spectral resolution of 4 cm⁻¹ and accumulated for 32 scans.

2.4. Transmission Electron Microscopy. Nanometric chemical and structural properties of ellestadite were examined by transmission

electron microscopy (TEM). Specimens were prepared by ultrasonically dispersing a small quantity of powder in ethanol then placing a drop of suspension on a holey carbon-coated copper grid dried in air. High-resolution transmission electron microscopy (HRTEM) was carried out at 200 keV with a JEOL 2100F TEM. Samples were orientated with a double tilting holder and the selected area electron diffraction (SAD) patterns recorded. Observation times were limited due to electron amorphization, especially when a more converged beam was used for imaging.

3. RESULTS AND DISCUSSION

3.1. Metalloid Speciation. The incorporation of fluorine did not obviously affect the FTIR spectra of chlorellastadite

Figure 5. Variation in cell parameters (a) a and c , and (b) unit cell volume with degree of fluorine substitution x in $\text{Ca}_{10}(\text{SiO}_4)_3(\text{SO}_4)_3\text{Cl}_{2-x}\text{F}_x$. Standard deviation of data is smaller than size of points. The open circles in (b) are taken from the literature^{11,12}.

(Figure 2). The sulfate ν_3 and ν_4 vibration modes were identified by three features (at 1138, 644, 615 cm^{-1}) as were the silicate ν_3 and ν_4 modes (at 938, 561, 508 cm^{-1}).²⁶ CO_3^{2-} incorporation, if present, was below the limit of detection. For $x = 0.4$ and 0.8 (x in $\text{Ca}_{10}(\text{SiO}_4)_3(\text{SO}_4)_3\text{Cl}_{2-x}\text{F}_x$), the OH^- librational mode appears very weakly at 660 cm^{-1} .

3.2. Quantitative Phase Analysis. Powder XRD shows that ellestadite is always dominant (>95 wt %) (Figure 3). Additionally, the reactants quartz SiO_2 (<0.5 wt %) or anhydrite CaSO_4 (<3.5 wt %) persist for low fluorine substituted samples.

3.3. Crystal Structure Analysis. The details of the crystal structures refinements including atomic positional parameters and temperature displacement parameters are given in Table 1, with selected atomic distances and bond angles collected in Table 2. The Rietveld refinement and difference Fourier maps show that across the fluor-chlorellestadite series, the halides occupy the $2a$ (F^-) or $4e$ (Cl^-) Wyckoff positions. The location of chlorine ions in the chlorellestadite endmember ($x = 0$) show nuclear scattering at $4e$ (0, 0, 0.431), while in fluorellestadite ($x = 2$), scattering at $2a$ (0, 0, $1/4$) was assigned to F^- (Table 1).

Figure 6. Partial X-ray powder diffraction patterns of ellestadites with $x = 0, 0.8, 1.6$. (x in $\text{Ca}_{10}(\text{SiO}_4)_3(\text{SO}_4)_3\text{Cl}_{2-x}\text{F}_x$).

Figure 7. Perspective drawing of $\text{Ca}(2)$ triangle arrangement on the screw axis (a) $x = 0.4$, and (b) $x = 1.6$. (x in $\text{Ca}_{10}(\text{SiO}_4)_3(\text{SO}_4)_3\text{Cl}_{2-x}\text{F}_x$) F^- lies in the center of $\text{Ca}(2)$ triangle on the mirror planes, while Cl^- splits into two half-occupied sites above or below the mirror plane. The interatomic distances are in Å. The distances between Cl site and the mirror plane ($z = 1/4$) are indicated by the dotted lines.

Similar bilocation was used for intermediate F/Cl compositions (Figure 4). The Cl^- position shifts from $z = 0.431$ in the endmember toward the mirror plane with increasing fluorine content ($z = 0.412, 0.382, 0.342$, and 0.336 for $x = 0.4, 0.8, 1.2$, and 1.6 , respectively) (Figure 7a). It is likely that the weak OH^- signature observed by FTIR arises from a nonellestadite phase, since a residual feature in the Fourier map cannot be assigned to hydroxyl, as suggested by FTIR for $x = 0.4$ and 0.8 , and if present, OH^- is in low abundance. Examination of the difference Fourier maps (Supporting Information Figure A1) exhibited low electron densities in the range of $-0.85 \text{ e}/\text{\AA}^3$ to $0.85 \text{ e}/\text{\AA}^3$, which discounts the possibility of multiple Cl^- positions¹⁵ or splitting of $\text{Ca}(2)$ site⁹ as suggested by earlier studies.

Figure 8. Dependence of (a) z_{Cl} and (b) twist angle on degree of fluorine substitution x in $\text{Ca}_{10}(\text{SiO}_4)_3(\text{SO}_4)_3\text{Cl}_{2-x}\text{F}_x$.

The Cl content was less than nominal for samples with $x \leq 1.2$. Halogen loss might occur during the solid state processing, as chlorine is susceptible to volatilisation, with possible charge compensation mechanisms being

Mechanism 1 is not supported by FTIR or structure refinement. In the case of mechanism 2, attempts to insert extra oxygen at additional (0, 0, z) positions on the hexagonal axis were unsuccessful, as the temperature displacement parameter of oxygen atom became negative. Prener²⁷ studied nonstoichiometry in calcium chlorapatite, and stated that synthetic chlorapatite (often $P2_1/b$) became hexagonal $P6_3/m$ when grown from the melt due to Cl deficiency created by loss of CaCl_2 . In our study, the formation of Ca and Cl structural vacancies (mechanism 3) is possible as CaCl_2 partially evaporates during sintering at 950 °C ($m_p(\text{CaCl}_2) = 782$ °C). This would be consistent with the smaller unit cell parameter a (9.6702(3) Å) and volume (555.09(4) Å³) of the

chlorellstadite endmember, compared with stoichiometric chlorellstadite ($a = 9.6773(3)$ Å, $V = 556.25(4)$ Å³) reported previously.⁹ To examine this question, the occupancies of calcium and chlorine were refined with the constraint $\text{Ca}^{2+} + 2\text{Cl}^- \rightarrow \square_{\text{Ca}} + 2\square_{\text{Cl}}$ applied in three ways: (i) the occupancies of Ca(1) and Ca(2) were jointly refined together with Cl, (ii) the Ca(1) site was constrained with Cl site, with the Ca(2) site fully occupied, and (iii) the Ca(2) site was released with Ca(1) fixed to full occupancy. In this way, any preference to create Ca-site vacancies within the framework or tunnel could be distinguished (Table 3). While the differences in refinement residuals are small, it does appear that for Cl-rich compositions, Ca(1) vacancies may be present, while for F-rich ellestadites the reverse is true. However, further analysis would be required. It is noted that modeling with the Ca(1) and Ca(2) sites fully occupied lead to substantially inferior residuals, and in addition, cannot charge balance halogen substoichiometry. On the basis of these assessments, the formulas for these compounds are most generally written as $\text{Ca}_{10-y}(\text{SiO}_4)_3(\text{SO}_4)_3\text{Cl}_{2-x-2y}\text{F}_x$, rather than the nominal $\text{Ca}_{10}(\text{SiO}_4)_3(\text{SO}_4)_3\text{Cl}_{2-x}\text{F}_x$.

Singular value decomposition (SVD) as adapted by Mercier et al.^{25,28} for the evaluation apatite structures, found the numerical stability of the Rietveld refinements was satisfactory: in particular, the tunnel site occupancy was reliable. Typical outputs (Supporting Information Table A1) from *SVDdiagnostic* of the preconditioned normal matrices for the models in which the Ca(1) and Ca(2) sites were refined simultaneously (see also Table 3), give condition numbers of around 10^2 – 10^3 indicative of good conditioning of the least-squares matrices, that confirms the occupancy factors refinements are reasonable and not over interpreted. Similar results were obtained if Ca(1) or Ca(2) were refined alone.

As the content of fluorine increases, a contracts while c dilates, but overall the unit cell volume is reduced (Table 1, Figure 5), because fluorine is smaller than chlorine. In addition, the splitting of the intense doublet reflections (121)/(211) and (112)/(030) in the chlorellstadite endmember pattern into a resolved triplet (121)/(211), (112), and (030) provides further confirmation of the mixed anion structure²¹ (Figure 6). The loss of CaCl_2 from the structure also contributes to unit cell shrinkage. According to Young and Elliott,²⁹ the small increase in c may be related to the different atomic positions of halogen ions. As fluorine is centered in the Ca(2) triangle ($z = 1/4$), it will not affect the c axes. However, chlorine is displaced >1 Å along c , weakly bonding to the neighboring calcium Ca(2) triangles that leads to slight contraction of the c axis.

Differences in the anion content of the tunnel negligibly disturbs the (Si/S) O_4 tetrahedra, which are essentially rigid bodies, and the Ca(1) O_9 polyhedra (Table 2). There are only minor changes in the (Si/S)–O bond lengths and no evidence for a Si/S ordering which would lower the symmetry to monoclinic. The refined mean bond length Si/S–O = 1.545 Å, close to the average value of 1.55 Å calculated from Si–O = 1.61 Å in silicates³⁰ and S–O = 1.49 Å in sulphates,³¹ is also consistent with a statistical distribution of SiO_4 and SO_4 tetrahedra.

The major structural response to fluorine substitution occurs in the Ca(2) $\text{O}_5(\text{F/Cl})(\text{O})$ polyhedron (a seventh weak bond to O(1) exists in fluorellstadite) (Table 2). As noted the Ca(2) atoms located on the mirror planes at $z = 1/4$ and $3/4$ form triangles that are centered around the $[001]$ $\bar{3}$ axis containing the F/Cl (Figure 7). The Cl^- ion located in 4e shifts from $z = 0.4315(3)$ in the chlorellstadite endmember toward the Ca(2) triangles as z decreases to 0.336(3) (Figure 8a).

Figure 9. Correlations observed between polyhedral distortion parameters: (a) δ_{Ca1} versus $\phi_{\text{O3-Ca2-O3}}$, (b) $\langle \tau_{\text{O-B-O}} \rangle$ versus $\phi_{\text{O3-Ca2-O3}}$, (c) $\Psi_{\text{Ca1-O1}}^{\text{Ca1}z=0}$ versus α_{Ca1} , and (d) α_{Ca2} versus $\phi_{\text{O3-Ca2-O3}}$. These figures should be compared with Figure 8 in Mercier et al.³³ Circles: published data; large filled squares: this study. (δ_{Ca1} : counter-rotation angle of CaO_6 polyhedra; $\phi_{\text{O3-Ca2-O3}}$: O3-Ca2-O3 bond angle; $\langle \tau_{\text{O-B-O}} \rangle$: O-B-O bond-bonding angle; $\Psi_{\text{Ca1-O1}}^{\text{Ca1}z=0}$: angle that an $\text{Ca1}_{z=0}\text{-O1}$ bond makes with respect to c ; α_{Ca1} : orientation of CaO_6 polyhedra with respect to a ; α_{Ca2} : orientation of Ca2 triangles with respect to a).

The interatomic distances between $\text{Ca}(2)$ and Cl decreased from 2.803(4) Å in the chlorellestadite ($x = 0$) to 2.421(6) Å when $x = 1.6$. The $\text{Ca}(2)\text{-F}$ bond length also follows this trend, decreasing from 2.474(5) Å in $x = 0.4$ to 2.3018(1) Å in fluorellestadite ($x = 2.0$) (Table 2). As the F^- ion lies in the center of the $\text{Ca}(2)$ triangle, the decrease of the $\text{Ca}(2)\text{-F}$ distances with reduction of chlorine content leads to a contraction in the unit cell a -parameter (Table 1, Figure 5b).

The metaprism twist angle (φ), defined as the (001) projected angle of the $\text{O}(1)\text{-Ca}(1)\text{-O}(2)$, was used to validate the Rietveld refined ellestadite structures (Table 2). The twist angle (φ) is related to the relative sizes of the A , B , and X ions³² and also sensitively detects disequilibrium and nonstoichiometry. In passing from fluorellestadite ($x = 2$) to chlorellestadite ($x = 0$), the twist angle (φ) decreases from 24.1° to 19.9°, with increasing chlorine content leading to a tunnel dilation and to increased $\text{Ca}(2)\text{-F/Cl}$ distances. The near linear change in twist angle (φ) is expected, and small departures from linearity

may be indicative of Cl deficient nature of some compositions (Figure 8b).

As further validation of the refined structures, the crystal-chemical parameters proposed by Mercier et al.³³ (Supporting Information Table A2) were extracted for the refined ellestadite structures; the geometrical derivation of these parameters can be found in this earlier work. The principle correlations among those crystal-chemical parameters, including data from this study and published work are shown in Figure 9. As the fluorine content increases, the $(\text{Si/S})\text{O}_4$ tetrahedra ($\tau_{\text{O3-Ca2-O3}}$ decreases) and CaO_6 polyhedra (δ_{Ca1} decreases) are distorted to accommodate the increase of the O3-Ca2-O3 bond angle ($\phi_{\text{O3-Ca2-O3}}$). These correlations conform to the trends observed by Mercier et al.³³ (Figure 8 in ref 33.), and of particular interest, fill a gap noted in their work for apatites with $131^\circ < \phi_{\text{O3-Ca2-O3}} < 135^\circ$. Furthermore, the crystal chemical parameters are clustered for F -rich compositions consistent with loss of Cl , and confirm there is little change in halide content for these materials.

Figure 10. (a) Wide field [001] HRTEM image of $\text{Ca}_{10}(\text{SiO}_4)_3(\text{SO}_4)_3\text{Cl}_{0.4}\text{F}_{1.6}$, (experimental, FFT and simulated SAED reflections are provided.) (b) The as-collected images (left) and processed image (right) constrained by $p6$ symmetry are shown.

None of the ellestadites show measurable deviation from the hexagonal metric. This behavior is distinct from the $\text{Ca}_{10}(\text{V}_x\text{P}_{1-x}\text{O}_4)_6\text{F}_2$ apatites,³⁴ which at the largest vanadium contents become triclinic. For these materials, the approach of α_{H} to 120° was seen to precede a reduction in symmetry. However, in these studies it was found that $\text{Ca}_{10}(\text{SiO}_4)_3(\text{SO}_4)_3\text{Cl}_2$ with $\alpha_{\text{H}} = 120.23^\circ$ could be convincingly modeled in $P6_3/m$. It has already been noted that mineral ellestadites may be monoclinic, and long annealing of synthetic $\text{Ca}_{10}(\text{SiO}_4)_3(\text{SO}_4)_3\text{Cl}_2$ may allow SiO_4/SO_4 ordering with stabilization as $P2_1/m$ or $P2_1$ structures.

3.4. Local Structure. A high-resolution TEM image of $\text{Ca}_{10}(\text{SiO}_4)_3(\text{SO}_4)_3\text{Cl}_{0.4}\text{F}_{1.6}$ shows a well developed crystal without obvious imperfection, in the sense that no extended defects are observed (Figure 10a). A comparison of the intensity distribution of experimental and simulated SAED reflections was consistent with $P6_3/m$ symmetry. The SAED pattern did not show split reflections, precluding the possibility of coexisting mixed-phase ellestadite,¹⁹ or localized order with respect to anionic sequences within the anion tunnels that would lower the symmetry to monoclinic. Fourier reconstruction of the images yield potential maps (Figure 10b) most plausibly constrained to the plane group $p6$ which is the [001] symmetry projection for $P6_3/m$. In the HR image, the darker feature represents the positions of $\text{Ca}(1)\text{O}_6$ polyhedral columns which share (001) pinacoid faces to form chains parallel to c , while the bright contrast corresponds to the anion columns at the tunnel centers.

4. CONCLUSION

The synthesis of fluorine-substituted chlorellestadites has been achieved by the solid state method, and the crystal structures refined via powder X-ray and neutron diffraction using $P6_3/m$ symmetry. Ordering of the Si and S atoms within the tetrahedra, or halides between the tunnels can be excluded, as this would lead to $P2_1/m$ or $P2_1/b$ structures respectively, with a possible doubling of the unit cell in the a or b directions. In natural ellestadites, described in $P2_1/m$ and $P2_1$, equilibration over very long geological periods may favor lower symmetry. For the synthetic ellestadites studied here, increasing fluorine content, leads to a progressive shift of Cl^- toward the center of the $\text{Ca}(2)$ triangle; the formation of a shorter, stronger bond between $\text{Ca}(2)$ and Cl may enhance the chemical stability of ellestadite. Minor loss of CaCl_2 during sintering induces Ca-vacancies within ellestadite was confirmed by powder neutron diffraction, and verified by the spread of $\text{Ca}(1)\text{O}_6$ metaprisms twist angles as a function of composition, although the overall trend is linear. For charge balance, halide vacancies in the anion tunnel were compensated by calcium vacancies, and may be required to provide structural accommodation for larger Cl ions, or reduce structural strain due to the mismatch of the framework and tunnel dimensions. The reliability of Rietveld refinements were evaluated by Singular Value Decomposition and correlations of various crystal–chemical parameters. Future reports will focus on compositionally complex ellestadites and chemical tailoring that improves the stability and effectiveness of waste form ceramics.
