Artificial photosynthesis by light absorption, charge separation, and multielectron catalysis

Miloš Đokić^a and Han Sen Soo^{*ab}

Our society's current energy demands are largely met by the exploitation of fossil fuels, which are unsustainable and environmentally harmful resources. However, Nature has provided us with a clean and virtually limitless alternative in the form of solar energy. This abundant resource is utilized constantly by photosynthetic organisms, which has in turn motivated decades of research in our quest to create artificial counterparts of comparable scales. In this Feature article, we will highlight some of the recent novel approaches in the field of artificial photosynthesis (AP), which we define by a more general term as a process that *stores energy overall by generating fuels and chemicals* using light. We will particularly emphasize on the potential of a highly modular plug-and-play concept that we hope will persuade the community to explore a more inclusive variety of multielectron redox catalysis to complement the proton reduction and water oxidation half-reactions in traditional solar water splitting systems. We discuss some of the latest developments in the vital functions of light harvesting, charge separation, and multielectron reductive and oxidative catalysis, as well as their optimization, to achieve the ultimate goal of storing sunlight in chemical bonds. Specific attention is dedicated to the use of earth-abundant elements and molecular catalysts that offer greater product selectivity and more intricate control over the reactivity than heterogeneous systems. In this context, we showcase our team's contributions in presenting a unique oxidative carbon-carbon bond cleavage reaction in aliphatic alcohols and biomass model compounds, under ambient atmospheric conditions, facilitated by vanadium photocatalysts. We offer this discovery as a promising alternative to water oxidation in an integrated AP system, which would concurrently generate both solar fuels and valuable solar chemicals.

1. Introduction

The "terawatt (TW) challenge" was coined in 2005 by the late Nobel laureate, Richard Smalley, to contextualize the scale of our energy requirements in the near future.¹ Currently, over 80% of global energy needs are satisfied by fossil fuels,² and the total energy demand is expected to increase by about 20% to 23 TW in 2030.^{3, 4} Furthermore, fossil fuels are limited, and the additional strains from pollution and global climate change due to fossil fuel combustion has led to an impending energy and environmental crisis.^{5, 6}

Nature has provided a blueprint and inspiration for averting and overcoming these energy and pollution crises.^{3, 4, 7-9} On average, solar energy reaches the Earth's surface at a rate of 120 000 TW, which is at least three orders of magnitude above what the global population uses now and will need in the foreseeable future.^{3, 10} To exploit this virtually unlimited resource, natural photosynthesis worldwide currently stores solar energy at a rate of around 120 TW.^{3, 4, 10} Photosynthetic organisms have evolved sophisticated biological processes, using exclusively earth-abundant elements

available in disparate ecosystems, to capture solar energy and store it in reduced carbon compounds.^{3, 4} In so doing, they have simultaneously achieved multiple functions that should instruct us, including the following aspects.

- (i) The storage of diffuse sunlight over a panchromatic spectral range into energy dense fuels. Although solar energy is plentiful, it is distributed over a broad surface area and electromagnetic spectrum.^{3, 4, 9} Yet photosynthetic organisms have been able to concentrate this energy into energetic small molecules.
- (ii) The spatial and temporal separation of energy collection versus energy use. The available sunlight varies with the location, season, time of the day, and the weather. By storing the energy within the chemical bonds of small molecules, Nature circumvents the need to manage or match the solar flux with utilization, as usually required in photovoltaics.^{10, 11}
- (iii) The one-directional multielectron charge separation across an interfacial membrane via thermodynamically and kinetically favorable and well-matched chemical processes. The chlorophyll chromophores absorb single photons and undergo single charge separation events, but are coupled with energetically downhill charge transfer reactions that kinetically outcompete undesired recombination

^b Solar Fuels Laboratory, Nanyang Technological University, 50 Nanyang Avenue, Singapore 639798.

processes.^{3, 4, 7, 8} Natural photosynthesis operates essentially with a molecular diode.

- (iv) The indirect energy storage on the reductive half-reaction in the form of partially reduced carbon (instead of nitrogen) compounds via kinetically more facile proton reduction processes. The primary light driven process in the reductive Photosystem I half-reaction is the generation of “hydride” equivalents from water to convert NADP^+ to NADPH , which is subsequently employed in carbohydrate synthesis in the dark Calvin cycle.^{3, 4, 7, 8} The two-electron reduction of NADP^+ and subsequent reduction of CO_2 are all kinetically accessible reactions with numerous stable intermediates.
- (v) The concurrent generation of an oxygenic atmosphere to support their own survival and those of other aerobic organisms in an equally productive and critical oxidative half-reaction. Energy is stored during water oxidation to O_2 , which can subsequently be released during aerobic respiration.

Nature has thus created a self-sustaining system from which we can derive insights and adapt to our contemporary demands.

Commensurate with the scale of the TW challenge, inter-university and even international consortiums have dedicated research efforts to the development of artificial photosynthesis (AP), with the intention of mimicking green plants to produce solar chemicals and ultimately solar fuels.¹² However, the term AP is traditionally often synonymous with solar fuels or water splitting, which may be unnecessarily restrictive. As the term suggests, AP is the invention of man-made (artificial) chemical or biological processes to harness light (photo) to produce *fuels and* chemicals (synthesis). To differentiate between photosynthesis and photocatalysis in this article, we will adopt a convention based on

thermodynamics and kinetics.¹³ Photocatalysis involves light as an energy input to accelerate rates by overcoming the kinetic barrier for reactions that are already thermodynamically downhill reactions, whereas photosynthesis requires light to drive reactions that are otherwise thermodynamically uphill. In other words, we use photosynthesis to refer to redox processes that will *store energy overall across two half-reactions*.

Tremendous progress has been reported in the field of AP, although the research has largely focused on solar fuels production through water splitting by semiconductor materials.^{14–17} On the other hand, molecular systems offer the advantages of systematic ligand design and modification, better product selectivity, and more comprehensive characterization.

Inspired by natural photosynthesis, our team has adopted an engineering “plug-and-play” concept to create AP constructs based on combining the functions of individual components (Fig. 1). A number of research groups and us have been exploring a more general perspective to use light to make chemicals, beyond H_2 and O_2 from water splitting. In this feature article, we will focus the discussion on the specific functions of photosynthesis, which can be distilled into the following four themes.

- (i) The productive absorption of sunlight, especially with panchromatic chromophores.
- (ii) The effective charge separation and interfacial chemistry to achieve a more systematic flow of reducing and oxidizing equivalents.
- (iii) The multielectron catalytic reduction of substrates to produce fuels.
- (iv) The multielectron catalytic oxidation of substrates to produce similarly value-added chemicals other than the

Artificial Photosynthesis by Light Absorption, Charge Separation, and Multielectron Catalysis

Fig. 1 Proposed general “plug-and-play” system for AP to encompass a more inclusive range of catalytic processes that can store sunlight in the form of chemical bonds in solar fuels and value-added solar chemicals.

atmospherically abundant O₂.

We will examine some of the latest research on optimizing the individual constituents of an integrated system, some of which have been assembled into AP units. This article is not intended to be a comprehensive coverage of the extensive field of AP, but will especially highlight molecular and hybrid molecular-material systems comprising exclusively earth-abundant elements.

2. Light absorption

Since the pioneering studies on water splitting with TiO₂,¹⁴ there has been impressive progress on using semiconductors as chromophores in AP system with work on nanostructuring and doping among the many popular routes. However, more comprehensive reviews about semiconductor photosensitizers and photocatalysts for AP have been discussed in greater detail elsewhere.^{18–20} Furthermore, porphyrin- and porphyrinoid-type sensitizers and their applications in AP have been exhaustively reviewed and will not be discussed in this article.^{8, 21–24} Instead, in the next few sections, we will focus on molecular chromophores

Fig. 2 Several classes of complexes comprising first-row transition metals such as Fe, Cr, and Cu recognized as photosensitizers. The lifetimes of the longest-lived variant to date in each class are highlighted. The structures and lifetimes have been summarized from references 31, 33 – 49, 53 – 57, and 59 – 64.

that can be employed in AP systems. In particular, we consider the most recently developed charge transfer-based complexes containing the relatively more abundant first row transition metals (Fig. 2), but also the unusual class of all inorganic, metal-to-metal charge transfer (MMCT) units as photosensitizers in AP.

2.1 Molecular light absorbers comprising earth-abundant first-row transition metals

The platinum group metal complexes have traditionally been the workhorse among photosensitizers used in AP, with the most widely used being ruthenium (Ru) polypyridyl complexes.^{25–27} Since Ru is a second-row transition metal with a stronger ligand field than the first-row elements, the Ru polypyridyl complexes typically exhibit a number of desirable properties for AP. This includes long-lived photoexcited states, high chemical stability due to the stronger metal-ligand bonds (and consequently reversible electrochemistry), and visible light absorption, to name a few.²⁸ Despite the long history of Ru photosensitizers, the groups of Hammarström and Berlinguette have only recently demonstrated that judicious ligand design to install a more idealized octahedral environment, coupled with the introduction of strong-field carbene ligands, can dramatically increase the excited state lifetime.^{29, 30} Nonetheless, there has been perennial interest in replacing platinum group metal complexes with more earth-abundant first-row transition metal counterparts such as iron (Fe), chromium (Cr), and copper (Cu)²⁸ with few non-porphyrinoid examples of the other elements due to their shortlived excited states.

In accord with expected periodic trends, there have been numerous attempts to prepare analogous octahedral Fe polypyridyl photosensitizers. However, although many Ru photosensitizers with triplet metal-to-ligand charge transfer (³MLCT) excited state lifetimes of at least 100 nanoseconds (ns) are known, there are currently still no instances of Fe complexes with photoexcited lifetimes above 100 picoseconds (ps).³¹ McCusker and coworkers proposed that a number of higher energy ligand-field states mediate the non-radiative relaxation of the ¹MLCT excited state to the ⁵T₂ excited state within less than 300 femtoseconds (fs) among most Fe photosensitizer candidates.³² Subsequently, the relaxation from the ⁵T₂ back to the singlet ¹A₁ ground state is also facile and non-radiative, highlighting how spin selection rules do not appear to inhibit the excited state intersystem crossing among transition metal complexes.³²

Progress has been made in moving beyond the paradigm of ³MLCT excited states accessed from low-spin d⁶ Fe^{II} complexes, directly analogous to the Ru congeners. Damrauer, Shores, and their coworkers adopted an alternative approach by introducing steric strain to prepare high-spin ⁵T₂ ground-state Fe^{II} bis(terpyridine) complexes (Fig. 2).^{33, 34} Remarkably, the photoexcited ⁷MLCT exhibits a lifetime of up to 17.4 ps, which is two orders of magnitude longer than the ³MLCT in the generic low-spin [Fe(bpy)₃]²⁺ (bpy = 2,2'-bipyridine) complex.^{33, 34} Although the short lifetimes preclude their use even in diffusion-controlled (~0.1 ns) intermolecular charge transfer reactions, Fe photosensitizers can still be productively employed in AP provided that the charge extraction rates exceed the non-radiative vibrational or

recombination processes. For instance, Wärnmark and his team have provided a roadmap for how novel *N*-heterocyclic carbenes (NHCs), such as those used in Berlinguette's Ru complexes, can be used to increase the photoexcited, doublet ligand-to-metal charge transfer (²LMCT) lifetime to around 100 ps at room temperature (Fig. 2).³¹ Moreover, they had previously shown that a NHC Fe complex could inject electrons into the conduction band of TiO₂ in a dye-sensitized solar cell (DSSC) within ~3 ps with quantum yields of up to 92%.³⁵ Clearly, there are still promising avenues to explore by using ligand design and ingenuity to prolong the MLCT or LMCT lifetimes of Fe-based photosensitizers for AP applications.

Besides Fe among the first-row transition metal series, octahedral Cr complexes have also been investigated in photochemical applications,³² presumably due to the established long-lived emissive properties in ruby lasers. A ⁴T₂ ground-state [Cr(Ph₂phen)₃]³⁺ (Ph₂phen = bathophenanthroline) complex with a 13 microsecond (μs) ²E excited state was reported to oxidize anethole to a radical cation during a photoredox Diels-Alder cycloaddition reaction (Fig. 2).³⁶ Even though the Cr^{III} complexes already possess synthetically practical μs lifetimes, Heinze and coworkers have employed ligand deuteration to shut down C-H vibrational overtone relaxation processes and prolong the lifetime of luminescent Cr^{III} polypyridine complexes up to a record of 2.3 milliseconds (ms)!³⁷ Another novel approach to use octahedral Cr complexes is the recognition that Cr⁰ is isoelectronic with Fe^{II}, opening up the possibility of accessing Cr⁰ photosensitizers. Wenger and coworkers developed bidentate, chelating diisocyanide ligands and accessed powerful Cr⁰ photoreductants with excited state redox potentials of -2.43 V vs Fc^{+/0} and lifetimes of 2.2 ns (Fig. 2).³⁸ These developments mark only the tip of the iceberg in the potential application of new first-row transition metal complexes for AP.

In addition to Fe and Cr, the most extensively studied first-row transition metal photosensitizers are Cu^I compounds. Similar to the aforementioned photosensitizers, the Cu^I complexes absorb light through MLCT processes and are consequently also supported by diimine ligands such as bipyridines and phenanthrolines (Fig. 2). Several other properties suggest that Cu^I photosensitizers can be viable competitors against the dominance of platinum group variants, including the following.

- (i) The smaller ligand fields facilitate tuning of the absorption and emission behavior in the visible region through systematic ligand functionalization and substitution. The donor properties, size, and substitution pattern will alter both the ground- and excited-state characteristics, allowing for panchromatic absorption to maximize utilization of the solar spectrum.^{28, 39, 40}
- (ii) The excited state redox potentials remain synthetically useful with suitable choice of ligands. In fact, the [Cu(dpp)₂]⁺ complex (dpp = 2,9-diphenyl-1,10-phenanthroline) is a stronger photoreductant than the archetypal [Ru(bpy)]²⁺, indicating that Cu^I photosensitizers possess similarly versatile photoredox chemistry.^{28, 40}

- (iii) The $^3\text{MLCT}$ excited states are sufficiently long-lived with similar ranges, in the same order of magnitude as the best Ru complexes.^{28, 40, 41}
- (iv) Cu is more earth-abundant and cheaper, making it an economically attractive replacement for platinum group metals.^{28, 39}

Despite all these benefits, Cu^{I} complexes suffer from some undesirable problems. Chief among them is the kinetic lability of the complexes due to the weaker metal-ligand bonds, which compromises their stability especially in coordinating solvents. Perhaps more critically, the excited state structural dynamics is distinct from the established octahedral Ru systems since Cu^{I} complexes typically have coordinatively unsaturated tetrahedral or pseudo-tetrahedral geometries. The generally accepted model for these four-coordinate d^{10} complexes is that after light absorption, the Franck-Condon MLCT state has a propensity to undergo a pseudo-Jahn-Teller flattening distortion due to the unequal occupancy of the almost degenerate d-orbitals (Fig. 3a).^{28, 39, 41, 42} Chen *et al.* combined fs optical transient absorption spectroscopy (TAS) with ps synchrotron-based X-ray pulses to elucidate the excited state structural evolution and confirmed that $[\text{Cu}(\text{dmp})_2]^+$ (dmp = 2,9-dimethyl-1,10-phenanthroline) indeed undergoes this flattening distortion.⁴¹ Within 500 fs, the initial MLCT state undergoes intersystem crossing to the flattened triplet, after which a five-coordinate exciplex can form under diffusion control (Fig. 3). X-ray absorption measurements indicate that a strong interaction with solvent molecules or counterions will quench the luminescence and dramatically shorten the excited state lifetime.⁴¹ These fundamental insights have paved the way for the development of Cu photosensitizers with longer-lived excited states and greater structural stability.

Having identified that a main factor for the debilitating nonradiative relaxation of the $^3\text{MLCT}$ excited states of Cu^{I} is the flattening distortion and exciplex formation, one approach is to introduce steric bulk to shield the metal center from coordinating ligands. In this regard, *sec*-butyl, isopropyl, and aryl groups have been introduced to the 2,9- positions of 1,10-phenanthroline to inhibit the exposure of the excited state $\text{Cu}^{\text{I}*}$ center to coordinating ligands (Fig. 2).^{39, 40, 43-49} Furthermore, through the use of poorly coordinating solvents such as dichloromethane, remarkably long-lifetimes of 2.80 μs with a photoluminescence quantum yield of 6.3% could be achieved for $[\text{Cu}(\text{dsbtmp})_2]^+$ (dsbtmp = 2,9-di(*sec*-butyl)-3,4,7,8-tetramethyl-1,10-phenanthroline).^{40, 43} Consequently, these long-lived Cu^{I} photosensitizers have now been directed towards productive photoredox carbon-carbon bond formation catalysis,⁴⁹ photochemical upconversion for solar cells,⁴⁸ and the production of solar fuels including H_2 .⁴⁶

Beyond phenanthrolines and bipyridines, other commercially available or synthetically more accessible ligands have recently received greater attention. Bidentate phosphines including bis[(2-diphenylphosphino)phenyl]-ether (DPEphos) and 4,5-Bis(diphenylphosphino)-9,9-dimethylxanthene (xantphos), chiral phosphines, and carbazoles have been used, sometimes simultaneously with phenanthroline ligands, to modulate the electronic structure and sterics of the Cu^{I} complexes (Fig. 2).^{47, 50-52}

Fig. 3 (a) Typical proposed pathway for the generation and decay of the MLCT photoexcited state of tetrahedral Cu^{I} complexes, with $[\text{Cu}(\text{dmp})_2]^+$ as a specific example. This figure has been reproduced with permission from Chen *et al.* Copyright 2003 American Chemical Society.⁴¹ (b) Simplified Jablonski diagram depicting the excited state processes of Cu^{I} complexes together with exemplary timescales. The lifetimes have been obtained from representative references 41 and 56.

Phosphines are soft and strong-field ligands able to support Cu^{I} complexes, and are ubiquitous due to their importance for synthetic organic coupling chemistry. Fu, Peters, and their team have demonstrated that Cu^{I} complexes generated in situ can be employed for photoredox inner-sphere carbon-carbon and carbon-nitrogen bond formation reactions.⁵⁰⁻⁵² A suitable choice of chiral phosphine can facilitate even asymmetric catalysis,⁵¹ showcasing how Cu^{I} photosensitizers are gradually being adopted in applications dominated by platinum group metal complexes.

In addition, our team and others have sought to incorporate the previous insights on chelating diimine ligands to introduce synthetically facile bis(arylimino)acenaphthene (Ar-BIAN) ligands to support Cu^{I} complexes (Fig. 2).⁵³⁻⁵⁶ Although Cu^{I} photosensitizers have photochemical performances on par with Ru complexes now, the steric and electronic criteria necessitates expensive and often multi-step functionalization of the commercially available

bipyridines, phenanthrolines, and phosphines. On the contrary, Ar-BIAN ligands are highly versatile and stable π -acceptors able to accommodate up to four electrons, and can be prepared in one step from condensation of a diverse number of cheap, sterically varied anilines with acenaphthenequinone.^{57, 58}

By prudent selection of ortho-substituted anilines, suitably bulky Ar-BIAN ligands can be prepared to stabilize Cu^I complexes against the excited state flattening distortion. Our team installed ortho iodo groups on Ar-BIAN ligands both for steric reasons and also to provide the heavy-atom effect to prolong the excited state lifetime (Fig. 2).⁵³ The resultant Cu^I complexes exhibited panchromatic light absorption extending to 1400 nm in the near-infrared (NIR) region, and were incorporated into DSSCs as a proof of concept.⁵³ Subsequently, the ligand and even the metal complex synthesis was improved through the use of essentially solvent-free mechanochemical ball-milling.^{59, 60} However, as Zysman-Colman and Tkachenko have observed previously, the significant spatial overlap between the frontier orbitals in the Cu^I complexes have created non-emissive triplet intraligand (³IL) states that quench the luminescence (Fig. 3b).^{54-56, 61-63} The synthetic ease of modifying Ar-BIAN ligands is a benefit to overcome these problems. Our team is

currently working with Zysman-Colman to functionalize the bay-region of Ar-BIAN ligands with electron-deficient groups to serve the dual purposes of localizing the spin density on the acenaphthene motif, and also provide anchoring groups for device applications.⁶⁴ We anticipate that our upcoming Cu^I photosensitizers will become appealing, more affordable candidates for light absorption in AP applications in the near future.

2.2 All-inorganic light absorbers

Although molecular first-row transition metal complexes have increasingly impressive photochemical characteristics, they still potentially suffer from the oxidative and kinetic instability prevalent among compounds supported by organic ligands. Moreover, retrieval and reuse of the dissolved photosensitizers could pose operational challenges in large-scale artificial photosynthetic systems. To overcome these issues, but still retain the chemical and photophysical selectivity of molecular units, some all-inorganic, discrete single-site chromophores that have been developed include polyoxometalates (POMs) and metal-to-metal charge transfer (MMCT) units (Fig. 4). POMs have been thoroughly reviewed and will not be included in this article,⁶⁵⁻⁶⁷ and the following section will largely focus on MMCT units as chromophores

Fig. 4 (a) Representative synthetic route, (b) Fourier transform of Mn K-edge EXAFS data (with an expanded region in the inset), (c) structural model, and (d) transient absorption spectroscopic data pumped at 420 nm and probed at 580 nm of Ti^{IV}OMn^{II} MMCT units. and photosensitizers.

One of our team has previously worked on a unique class of heterogeneous and yet are *bona fide* molecular photosensitizers in the form of MMCT units.^{68, 69} MMCT units are all inorganic, heterobinuclear chromophores bridged by a μ -oxo between two transition metals.⁷⁰⁻⁷² These thermally robust units are embedded on the surfaces of mesoporous silica, but can conceivably be installed on any stable metal oxide with suitable precursors. They typically consist of an electron acceptor like d^0 Ti^{IV} or Zr^{IV} , coupled with an electron donor including Cr^{III} , Mn^{II} , Fe^{II} , Co^{II} , Cu^{I} , and Ce^{III} .^{68, 69, 71-83} By astutely selecting the electron acceptor and donor, the redox potentials of the electron donor and acceptor can be tailored towards AP, with absorption onsets from the UV to visible regions. More comprehensive reviews have been published and only a cursory discussion about the synthesis, characterization, and reactivity studies with select MMCT units will be elaborated in this article to highlight their apt features for AP.

The preparation procedure involves grafting the two metals sequentially and taking advantage of the more acidic $Ti-OH$ or $Zr-OH$ over silica $Si-OH$ protons to selectively assemble the MMCT units (Fig. 4a). Titanocene and zirconocene complexes have been cheap, common, and convenient precursors to graft on the silica at less than 2 mol% of transition metal to silicon to ensure isolated units.^{69, 74-76, 79-81, 83} The organic ligands are then removed by calcination, after which a halide complex of the electron donor (e.g. $MnCl_2(CH_3CN)_2$) can be selectively deposited adjacent to the electron acceptor by using no base or a weak organic base such as triethylamine (Fig. 4a).^{74, 83} The remaining solvents or non-oxo ligands can then be removed by annealing *in vacuo* at moderate temperatures up to 350 °C.^{74, 83} The elemental ratios can then be verified by ICP-MS measurements, with the relative compositions of electron donor and acceptor usually below a factor of 2.^{74, 83}

The MMCT units characteristically have broad absorption profiles from the UV and extend into the visible region, due to the heterogeneity and distribution of the MMCT sites on the surface of silica (Fig. 4e).^{68, 71-76, 79-81, 83} The absorption band attributable to the MMCT motif only can be estimated by subtracting the normalized contributions from just a superposition of the LMCT bands of the electron acceptor and the d-d transitions from the electron donor.^{68, 71-76, 79-81, 83} The panchromatic absorption allows effective harvesting of the solar spectrum. The oxidation states of the constituent metal centers were determined by X-ray absorption near edge structure (XANES) measurements.^{74, 76, 80, 83} More crucially, the integrity of the MMCT units could be evaluated by extended X-ray absorption fine structure (EXAFS), which provided the metal-metal bond distances and the bond angles of the $Ti^{IV}OMn^{II}$ and $Zr^{IV}OCu^{II}$ examples (Fig. 4b and 4c).^{68, 69} Besides steady-state spectroscopic characterization, the excited state lifetime had been measured by ns TAS and remarkably long lifetimes of up to 2.4 μs for the $Ti^{IV}OMn^{II}$ were observed (Fig. 4d).^{73, 82}

With the long-lived excited states in some of these MMCT units, they have been successfully applied in photoredox catalytic reactions.⁷⁷ Nakamura *et al.* have exploited a $Ti^{IV}OCe^{III}$ MMCT to harvest light for the oxidation of isopropanol to acetone and CO_2

with O_2 ,⁸⁴ whereas a $Ti^{IV}OMn^{II}$ MMCT could oxidize methanol to methyl formate.⁸³ In a series of studies, the Frei group has demonstrated the application of these MMCT units for water oxidation and CO_2 reduction catalysis. A $Zr^{IV}OCu^{I}$ chromophore was first shown to reduce CO_2 to CO stoichiometrically with

Fig. 5 (a) Simplified Z-scheme highlighting only the essential light absorption, electron flow direction, and multielectron H_2O oxidation and CO_2 reduction aspects. concomitant oxidation to Cu^{II} in a one-photon, two-electron process (355 nm irradiation).⁸¹ Subsequently, a $\text{Zr}^{\text{IV}}\text{OCo}^{\text{II}}$ MMCT could reduce CO_2 to CO and formate,⁶⁸ and the same MMCT when coupled with Cu_2O nanocrystals could catalytically reduce CO_2 to CO with amines as the sacrificial electron donor.⁷⁸ For the oxidative half-reaction, IrO_x nanoparticles were loaded by impregnating mesoporous silica containing $\text{Ti}^{\text{IV}}\text{OCr}^{\text{III}}$ sites with $\text{Ir}(\text{acac})_3$ followed by mild calcination.⁷⁵ On irradiating these composites with 460 nm laser light in a buffered aqueous solution with persulfate as the acceptor, O_2 evolution with a 13% quantum efficiency was observed.⁷⁵ Using the combined insights from these studies, a visible-light driven catalytic cycle for simultaneous water oxidation and CO_2 reduction to CO was achieved with a $\text{Zr}^{\text{IV}}\text{OCo}^{\text{II}}$ MMCT connected to IrO_x nanoclusters.⁷⁹ Isotope labelling studies confirmed the origin of the CO was from CO_2 and O_2 was from H_2O (Fig. 4f).⁷⁹ These instances underscore how the inorganic, robust MMCT units can fulfil many of the criteria as the one-electron photosensitizers for powering multi-electron catalysis in integrated AP systems when suitably selected co-catalysts are present.

3. Interfacial chemistry and charge separation

In his early exposition on creating AP systems, Calvin proposed a “Z-scheme” in a vesicle, where light absorption and charge separation could take place across a phospholipid membrane (Fig. 5a).⁷ His prescience derived from insights of the fundamental workings of natural photosynthesis now motivate several approaches to independently optimize the charge separation and catalysis across a physical barrier to separate the products. In biological photosynthesis, the chlorophyll P680 absorbs light as the photosensitizer and initiates a cascade of energetically downhill and kinetically favorable electron transfers through mediating small molecules across a biological membrane to Photosystem I (PS I).^{3, 4, 9} On the oxidation side, a tyrosine is oxidized via PCET to a tyrosine radical, which in turn injects holes into the OEC (Fig. 5a).^{3, 4, 9} Through such a mechanism, Nature is able to absorb single photons, separate the charges over long distances, and drive O_2 evolution and solar fuels production across a lipid membrane. This understanding has led to technologies that parallel this kinetically driven interfacial charge separation process such as DSSCs and more lately, dye-sensitized photoelectrosynthesis cells (Fig. 5).^{25, 85, 86} Notably, however, majority of the semiconductor-molecule interfacial systems involve chemisorption through charged functional groups such as carboxylate, phosphonate, catecholate, hydroxamate, thiols, and thiocarbamate (Fig. 5d).^{25, 85-89} Although these anchoring motifs are very prevalent, they are notorious for their hydrolytic instability and limited applicability to metal oxide surfaces, in addition to being already extensively reviewed.^{88, 89} Here, we examine some of the recent covalent deposition approaches that apply to other material surfaces.

3.1 Interfacial anchoring groups for non-oxide materials

Other than metal oxides, there is increasing interest in grafting molecules to other materials such as silicon, gallium phosphide (GaP), carbon nanotubes, graphene, or graphite electrodes. Recently, Yano, Sharp, Moore, and their colleagues reported a robust protocol to graft and polymerize ligands on p-type GaP and

nanostructured indium tin oxide (ITO).⁹⁰⁻⁹⁵ In their earlier work, the GaP was first hydroxylated by etching with buffered hydrofluoric acid, after which 4-vinylpyridine was anchored by UV irradiation and subsequently photopolymerized (Fig. 6a).^{93, 95} This procedure essentially results in polyvinylpyridine chains covalently bound via alkoxide termination to the GaP surface. Successful grafting was confirmed by a suite of methods including grazing angle attenuated total reflection Fourier transform infrared spectroscopy, X-ray photoelectron spectroscopy (XPS), and XANES (Fig. 6).^{93, 95} There are several versatile features about this concept.

- (i) The polyvinylpyridine chains are suitable ligands to axially coordinate complexes such as the renowned cobaloxime H_2 evolution catalysts. The Co-modified material then becomes an effective photocathode for the photoelectrochemical (PEC) production of H_2 in neutral aqueous conditions (Fig. 6a).^{93, 95} Moreover, the multiple pyridine groups promotes self-regeneration even when the cobaloxime is detached

Fig. 6 Reaction scheme for anchoring pyridine ligands and subsequently, cobaloxime complexes on GaP by conversion of terminal alkenes to covalently bound polymer chains. (b) FT-IR spectra illustrating the successful attachment of cobaloxime on GaP with diagnostic peaks at 1240 and 1558 cm^{-1} from the complex. (c) XPS data of the Co 2p binding energies showing that the cobaloxime remains intact after grafting before and after H_2 evolution experiments in a PEC geometry. during the catalysis.

- (ii) The choice of ligand can be varied conveniently using different commercially available vinyl-substituted ligands. Instead of 4-vinylpyridine, *N*-vinylimidazole was applied in similar fashion to create polyvinylimidazole chains on GaP that were also effective ligands for cobaloxime.⁹⁰ This new Co-modified GaP material was also suitable for H₂ evolution in a PEC architecture.⁹⁰
- (iii) Other vinyl-substituted compounds, including metal complexes can be directly deposited. Co and Fe porphyrins with vinyl groups on the periphery were attached to GaP, and the modified semiconductors were in turn employed as the photocathode for H₂ generation in buffered water solutions.⁹²
- (iv) The surface is not limited only to GaP. The same approach was utilized to anchor cobaloxime and polyvinylpyridine to ITO.⁹⁴

Patently, this UV mediated anchoring procedure is widely applicable, at least for the reductive half-reaction in AP.

Another general approach to functionalize materials involves the transformation of ortho-phenylenediamine derivatives to become pyrazines after condensation with ortho-quinone edge sites of carbon electrodes.⁹⁶ Surendranath's team disclosed a general approach to covalently anchor redox active small molecules on the edge planes of graphitic carbon electrodes.⁹⁶ Likewise, the electrode materials were all thoroughly characterized by XPS, XANES, and electrochemistry.⁹⁶ This strategy has been used to effectively create a number of electrocatalysts for O₂ reduction in alkaline solutions,⁹⁷ CO₂ reduction with Re catalysts in acetonitrile,⁹⁸ and potentially photoredox reactions as well.⁹⁹ Since AP systems involve not only photocatalysis but also encompass electrocatalysis, this simple but robust modification of carbon-based electrodes can provide practical and timely solutions for PECs and other integrated systems.

3.1 New materials and approaches for directed charge separation

In order to couple single photon light absorption to multielectron catalysis, the photosynthetic Z-scheme bridges PSII and PSI with a sophisticated system of potentially matched small molecule intermediates so that charge separation is both kinetically and thermodynamically favoured over recombination. The Z-scheme thus behaves as a very effective molecular diode. To mimic these functions, the groups of Gust, Thomas and Ana Moore, Fukuzumi, and Hammarström have created molecular dyads, triads, and more complex units to segregate light absorption and create long-lived charge separated states that perform biomimetic catalytic activities. Carotenoid-porphyrins, carotenoid-porphyrin-fullerene/quinones,^{3, 8, 22, 100-102} and donor/acceptor-Ru(bpy)₃-catalyst molecular constructs¹⁰³ have been synthesized and some show almost unity quantum efficiencies for light absorption and charge separation. Some of these triads exploit the large driving force of recombination in the Marcus inverted region to produce long-lived excited states with almost unity quantum yields,^{3, 8} while others harness concerted proton and electron transfer to accelerate slower stepwise pathways.^{100, 101} Although many of these systems

are molecular masterpieces, the synthetic challenges in their construction deter adoption in large-scale AP units. Nonetheless, there has been a growing body of work, which has established that charge interchange between molecules and semiconductors, especially metal oxides, can be several orders of magnitude faster than recombination.^{22, 25, 85-87, 103, 104} Consequently, this has inspired us¹⁰⁵⁻¹⁰⁸ and others to seek new materials and architectures (Fig. 7) to effect the long-lived charge separation to drive multielectron

catalysis for AP.

Since the isolation of graphene and other 2D materials, carbon-based semiconductor materials have lately garnered much attention because they are earth-abundant, absorb visible light, and are easily synthesized. In particular, carbon nitride (CN_x) has found widespread applications for photocatalysis and AP since the first report on its visible light absorption for H_2 evolution, albeit with Pt as the co-catalyst (Fig. 7a).¹⁰⁹ Since then, Reisner, Lotsch, and coworkers have increased the rate of H_2 evolution and external quantum efficiency by introducing DuBois's exceptional Ni [P2N2] catalysts on CN_x ¹¹⁰ as well as carbon quantum dots.¹¹¹ The molecular Ni catalysts appear to extract electrons efficiently despite being only physisorbed to the CN_x .¹¹⁰ Most remarkably, the H_2 evolution has been coupled with benzylic alcohol oxidation to benzaldehyde (Fig. 7c), which creates a closed redox cycle for both a solar fuel (H_2) and a solar chemical (benzaldehyde).¹¹⁰ This concept of generating two value-added products will be further

explored in the following sections on multielectron catalysis.

Another interesting adaptation of CN_x is the use of a cyanamide-functionalized heptazine polymer as a photocapacitor to store solar energy.¹¹² The CN_x was able to capture visible light under an anaerobic environment and turn from yellow to blue in the presence of electron donors (Fig. 7b).¹¹² After the irradiation ceased, the CN_x stored the trapped photoelectrons for up to several hours. Critically, the stored charges could be released in the dark by introducing a co-catalyst such as colloidal Pt, resulting in H_2 release.¹¹² This work demonstrates a key principle of temporally separating light absorption, charge separation, and catalysis in natural photosynthesis by storing the charges as long-lived radicals in durable and recyclable CN_x materials.

Likewise, one of our team had previously been involved in the development of a molecular diode to achieve independent light absorption and charge separation across a proton conducting membrane (Fig. 8). In both natural and artificial photosynthesis,

Fig. 8 (a) Schematic of the photosensitization of $[\text{Ru}(\text{bpy}(\text{CO}_2\text{Me})_2)_3]^{2+}$, oxidative quenching by $[\text{Co}(\text{NH}_3)_5\text{Cl}]^{2+}$, followed by hole injection into Co_3O_4 - SiO_2 core-shell nanoparticle, mediated by the PV3 molecular wire. (b) Chemical processes leading to hole injection into PV3 after photoexcitation. TAS data after excitation at 450 nm and probing at 600 nm illustrating (c) the formation of the PV3^+ radical cation on the insulating SiO_2 control after hole injection by Ru^{III} , and (d) the absence of any PV3^+ radical cation on the Co_3O_4 - SiO_2 core-shell nanoparticle due to subsequent hole injection into Co_3O_4 within the instrumental time resolution. These figures are adapted from reference 114. (e) Rapid-scan FT-IR data depicting the hole injection by Ru^{III} and recovery of Ru^{II} into the Co_3O_4 - SiO_2 core-shell nanoparticles with PV3 molecular diodes (left) and the persistence of Ru^{III} even after 15 s for particles without PV3 (right). This figure was adapted from reference 117. Model showing the separated H_2O oxidation and CO_2 reduction (f), TEM (g), and EDX elemental map (h) of the Co_3O_4 - SiO_2 core-shell nanotubes containing embedded PV3 molecular diodes, adapted with permission from Edri *et al.*¹¹⁸ Copyright 2018 American Chemical Society.

proton gradients build up during H_2 evolution or water oxidation. It is thus essential that the reductive and oxidative half-reactions should have proton conducting conduits in between. Co_3O_4 is an established and effective water oxidation catalyst,¹¹³ while silica can be a proton-conducting nanomembranes. To overcome the insulating behavior of silica, we embedded oligo(phenylenevinylene) with three aryl units (PV3) within the silica to function as hole-conducting diodes (Fig. 8a).¹¹⁴ PV3 molecules have lowest unoccupied molecular orbital (LUMO) potentials of -1.7 V relative to the standard hydrogen electrode (SHE), whereas they can be oxidized around +1.3 V vs SHE (Fig. 8b).¹¹⁴ Therefore, we anchored PV3 molecules on Co_3O_4 nanocrystals with a dehydration reaction and formed a thin silica shell around the units to create a core-shell structure (Fig. 8a).¹¹⁴ A similar construct with SiO_2 nanocrystals as the core was prepared as an insulating control specimen. Through the use of ns TAS and rapid-scan FT-IR experiments, we demonstrated that a long-lived PV_3^+ radical cation could be observed when $Ru(bpy)_3$ derivatives were irradiated and used to inject holes into the silica-only PV_3 core-shell constructs (Fig. 8c-e).^{114, 115} On the contrary, since the PV_3^+ radical cation would be thermodynamically favored to inject holes into Co_3O_4 , the PV_3 spectral signature was quenched within the time resolution of the instrument (Fig. 8d), implying that hole injection had taken place within 1 μs .^{114, 115} Most remarkably, this study was a proof of concept that we were able to absorb visible light and inject charges across an insulating membrane, providing an opportunity for us to separate the products from both the reductive and oxidative half-reactions.

Nonetheless, a spherical core-shell system with the Co_3O_4 core is unsuitable as a catalytic system since the water molecules will be unable to access the active sites. Moreover, the thickness of the silica shells in the original solvothermal synthesis processes cannot be precisely controlled. To address these issues, atomic layer deposition (ALD) has been used to create well-defined Co_3O_4 thin films coated with thin silica shells with PV3 embedded within.¹¹⁶ Electrochemical measurements confirmed that hole injection by $Ru(bpy)_3^{3+}$ was feasible when the PV3 molecular diode has been embedded, and the silica shell was free of pinholes.¹¹⁶ Ultrafast TAS experiments on these systems further indicate that chemisorbed porphyrin dyes can inject holes into PV3 within less than 1 ps, while the onward hole transfer to the Co_3O_4 occurred in 250 ps.¹¹⁷ Recently, silicon (Si) nanorod arrays have been employed as the template for ALD of Co_3O_4 and PV3 embedded silica shells, after which the Si was etched to leave behind arrays of Co_3O_4 -silica core-shell nanotubes (Fig. 8).¹¹⁸ It is anticipated that these hole-conducting molecular diode systems will eventually be integrated as crucial constituents of artificial photosynthetic units with high-fidelity unidirectional charge transfer between the multielectron catalytic reductive and oxidative half-reactions, akin to natural photosynthesis.

4. Multielectron catalysis

Although light absorption and charge separation are indispensable elements for an AP system, the energy must ultimately be stored in the form of fuels or chemicals. A clean and sustainable fuel and

platform chemical is H_2 , which produces water as a benign product after combustion or in a fuel cell. There are several challenges that hinder widespread adoption of H_2 as fuel, including the low volumetric energy density and the source of H_2 . For the former, there are ongoing efforts to develop new materials to store compressed H_2 that will not be covered here. Regarding the latter, majority of the H_2 is still generated from fossil fuels, especially by steam reforming of natural gas and coal gasification with the water gas shift reaction. The small remaining fraction is derived from electrolysis of water, but the commercial standard electrode is still predominantly the expensive platinum (Pt). Against this backdrop, there is an urgent need to develop more affordable catalysts for the water reduction reaction so that electrocatalytic or photocatalytic H_2 evolution can be price-competitive with H_2 from fossil fuels.

With these constraints in mind, there have been many opportunities to discover new materials and molecular catalysts for cost-effective H_2 evolution. A number of non-precious metal alloys, chalcogenides, phosphides, nitrides, and carbides, including 2D materials have been found to be efficient proton reduction electrocatalysts with overpotentials similar to Pt and comparable Tafel slopes.¹¹⁹⁻¹²¹ Likewise, there are molecular catalysts composed of only earth-abundant elements that perform with exceptionally high turnover frequencies (TOFs) and turnover numbers (TONs).^{122, 123} A comprehensive coverage of all these catalysts is beyond the scope of this article. Instead, we will limit the discussion to the following aspects. Foremost, only molecular catalysts comprising earth-abundant elements will be examined. In addition, we will focus mainly on H_2 evolution from aqueous or mixed organic-aqueous media. If H_2 is to be produced practically from photo- or electrocatalysis, the most abundant feedstock is water, especially seawater. Finally, we will showcase subtle aspects of second coordination sphere and other ligand participation effects where our team has contributed in. There are now many functional H_2 evolution catalysts and fundamental studies and judicious ligand design will be necessary to tease out further performance improvements in the future.

4.1 Electrocatalytic reduction for solar fuels and environmental remediation

In Nature's [FeFe] hydrogenases, the thermodynamics of heterolytic H_2 cleavage is poised at almost exactly 0 kcal mol⁻¹ so that they behave as the prototypical Sabatier-type catalysts, where the substrate binds exactly "just right".¹²⁴ One of the features that have been proposed to modulate the [FeFe] hydrogenase's ability to modulate the catalysis so precisely is that the dithiolate ligand bridging the two Fe centers may have an amine to function as a proton shuttle for the enzyme.¹²⁴ This intramolecular base or hydrogen-bonding that is in close proximity to the Fe active site facilitates the heterolytic cleavage of H_2 to form a hydride Fe-H without a high kinetic barrier.¹²⁴ Conversely, the amine also promotes H-H bond formation and hence H_2 evolution. These insights have in turn motivated the exploration of many bioinspired structural and functional mimics bearing amines as the second sphere proton shuttles (Fig. 9a).¹²⁵

Some of the most outstanding specimens of this approach are the [P2N2] Ni complexes from DuBois and lately, the Bullock team

at Pacific Northwest National Laboratory.¹²⁶ The [P2N2] ligands are bidentate and consist of two phosphines that the Ni, with two pendant aryl or alkyl amines that serve as the proton shuttle (Fig. 9a).¹²⁶ Each Ni complex binds two such [P2N2] ligands to form square planar [P2N2]₂Ni^{II} complexes.¹²⁶ The Ni^{II} pre-catalysts can be sequentially reduced to Ni⁰ and protonated on the amines during electrocatalytic H₂ evolution.¹²⁶ Through a series of detailed mechanistic studies, it was found that the Ni complexes can cycle through five oxidation states from Ni⁰ up to Ni^{IV} with the same ligand set.¹²⁶ Most impressively, the variant with phenyl substituents on the amines can operate with TOF of 106,000 s⁻¹ in

1.2 M water in acetonitrile, purportedly due to the position and pK_a of the proton relay!¹²⁷ In another functional parallel with [FeFe] hydrogenases, Shaw and coworkers installed arginines on the amine side-arms and showed that the new Ni electrocatalysts could oxidize H₂ with TOF of 144,000 s⁻¹, albeit at 133 atm of H₂ and an overpotential of 460 mV (Fig. 9a).¹²⁸

Building upon the fantastic H₂ evolution activity offered by the [P2N2]Ni^{II} catalysts, Reisner, Lotsch, and Durrant have incorporated them into photocatalytic systems using Ru and novel earth-abundant material-based photosensitizers. Both purely molecular Ru and Ru-sensitized TiO₂ were shown to be effective for

Fig. 9 (a) Recent examples using second-coordination sphere approaches to enhance H₂ evolution catalysis.^{125–131,137–139} The features of each class of catalysts are emboldened and explained below the structure. (b) Crystal structure of the Ni^{II} electrocatalysts possessing polyether chains without (left) and with K⁺ cations developed by our team. Cyclic voltammetry (c) and controlled potential electrolysis (d) with our Ni^{II} catalyst comparing the effects of different electrolytes. (e) H₂ evolution from seawater enhanced by our Lewis acid-binding Ni^{II} catalyst. The crystal structures and electrochemical data have been reproduced from reference 137.

photocatalytic H_2 evolution with photon-to- H_2 quantum yields of up to 10%.^{129, 130} In related studies, carbon quantum dots and CN_x materials were employed as the light absorbing and charge separating elements to achieve TONs above 1000 over several days.^{110, 111, 131} These H_2 evolution units represent some of the state-of-the-art in assembling the individually optimized components, exploiting vital second coordination sphere proton shuttle effects, into plug-and-play constructs.

In the same vein, the groups of Nam, Fukuzumi,¹³² and Agapie¹³³ discovered that redox inactive metals such as the alkaline earth elements, Zn^{II} , Sc^{III} , and Y^{III} can be integrated into the second coordination sphere to fine-tune the redox properties and oxidative reactivity of high-valent Mn and Fe complexes. Motivated by these prior insights, our team sought a robust catalyst that could harness the abundance of alkali metal cations in seawater for proton reduction. The role of alkali metal cations as second sphere Lewis acids for binding CO_2 in Co salen and salicylaldimine ("salen-type") complexes has been established since the 1970s.¹³⁴⁻¹³⁶ We considered if salen-type Ni complexes could be suitably modified with polyether chains to more effectively bind cations like Na^+ and K^+ that are ubiquitous in seawater. Gratifyingly, our Ni^{II} complex decorated with methoxy-ethoxy chains at the ortho position of the phenoxy ring could indeed bind alkali metal cations, as verified by solid-state crystal structures and UV-visible measurements in solution (Fig. 9a and 9b).¹³⁷ By using electrodes with high overpotentials for H_2 evolution such as mercury pool and carbon paper, we observed with cyclic and linear sweep voltammetry that the catalytic current increased by a factor of 11 on going from tetrabutylammonium to lithium cations as the electrolyte (Fig. 9c).¹³⁷ In addition, a similar enhancement was recorded during controlled potential electrolysis in both neutral and acetic acid aqueous solutions (Fig. 9d). Ultimately, H_2 evolution from filtered seawater was quantified with Faradaic efficiencies of around 82% (Fig. 9e).¹³⁷ Although seawater is typically more concentrated in electrolytes, it contains trace quantities of many ions that could poison catalysts, but not in our case. Our demonstration has thus highlighted a new approach to utilize second coordination sphere effects to encapsulate alkali metal cations and direct water molecules to be in close proximity with the redox-active catalytic center.

Another strategy adopted by Sun, Wang, and coworkers is to utilize hydrogen-bonding effects of peripheral alcohol groups to improve proton reduction catalysis. They discovered that Fe, Co, and Ni complexes formed in situ with triethanolamine (TEOA) as the ligand performed as stable H_2 evolution catalysts (Fig. 9a).¹³⁸ One of the arms of TEOA is not bound and could act as a hydrogen bond donor or proton donor. Using CN_x as the visible-light photosensitizer, the activity of the Ni complex was sustained for at least 60 hours from unbuffered TEOA solutions.¹³⁸ They extended this design principle to a different ligand set of tetraphosphines (" P_4N_2 ") bearing several pendant alcohol groups (Fig. 9a).¹³⁹ Remarkably, the in situ formed CoP_4N_2 catalyst can operate with an onset potential of merely 80 mV and has a TON of around 92,000 over 20 h in neutral phosphate buffer solutions.¹³⁹ A series of control experiments including a rinse test and the use of mercury electrodes indicate that the catalytic activity is homogeneous.¹³⁹

This catalytic system has in turn set a new landmark for high TONs and TOFs at low overpotentials, suggesting that thoughtfully designed molecular H_2 evolution catalysts may eventually be competitive with Pt in fuel cells or other applications.

4.2 Photocatalytic oxidation for solar chemicals

The envisioned plug-and-play concept allows for a highly modular system in which a variety of oxidative and reductive half-reactions can be combined into suitable AP systems. Apart from the water oxidation reaction, which has been an integral part of many water splitting AP units, we aimed to investigate other photooxidative transformations that can supply electrons for the reductive half-reaction and result in value-added solar chemicals production. In this section, we will consider photocatalytic oxidation to achieve solar chemicals, with an emphasis on the use of earth-abundant constituents.

The water oxidation half-reaction is kinetically and thermodynamically challenging since it involves multiple electron and proton transfers, and usually produces O_2 , an abundant gas with limited commercial value. Hence, there have been some efforts to develop scalable oxidative half-reactions commensurate with the electron demand for solar fuels production. For instance, Meyer and co-workers have been adapting their DSPEC architecture to target the oxidation of earth-abundant halides, namely bromide

Fig. 10 (a) Structure (left), spatial distribution of HOMO (center), and crystal structure (right) of our original V^{V} photocatalyst, adapted from reference 149. (b) Crystal structures of some of our faster and more robust V^{V} photocatalysts containing NO_2 and F substitutions. The ORTEPs have been adapted from reference 150.

and chloride.^{140, 141} They employed cationic, visible light absorbing Ru^{II} polypyridyl photosensitizers and complexes to form ionic donor-acceptor interactions with halide ions and bring them in close proximity to the catalytic center.¹⁴² After the halide photooxidation reaction, the X₂ molecules would be released due to the absence of Coulombic interactions.¹⁴² In the case of chloride oxidation, the reaction product was indirectly determined to be chlorine atoms via the use of 2,3-dimethyl-1,3-butadiene as a halogen trap.¹⁴¹ They have also applied their DSPEC for HBr splitting en route to the simultaneous generation of H₂ as a solar fuel and Br₂ and Br₃⁻ as solar chemicals.¹⁴³ Notably, however, the DSPECs predominantly comprise Ru photosensitizers and catalysts, which will offer future opportunities for replacement with earth-abundant variants instead.

As another alternative to water oxidation, Reisner and co-workers have reported a system that replaced water oxidation with alcohol oxidation, and coupled it with H₂ production to form an AP unit with concurrent solar chemicals and solar fuel generation.¹¹⁰ As introduced previously, a cyanamide surface-functionalized melon-type CN_x is the light harvester that oxidizes 4-methylbenzyl alcohol to the corresponding benzaldehyde through the photogenerated holes, while electrons are funnelled to a [P2N2]Ni^{II} catalyst, which performs as the H₂ evolution catalyst.¹¹⁰ This study represents an outstanding integrated catalytic redox cycle free of expensive noble metals with almost 100% atom economy and yields value-added products for both half-reactions, showcasing the feasibility of

accomplishing functional and effective AP using exclusively earth-abundant elements.¹¹⁰

In some novel developments lately, there has been greater political and economic pressure to reduce our dependence on finite fossil fuels and harness the under-utilized but sizable quantities of biomass as renewable sources of carbon. Biomass is often treated as fuel currently, which destroys the inherent valuable functional groups in the original form. Moreover, the biomass-derived feedstocks produced in large scale often possess low value, which can be increased in further transformations. Thus, they represent suitable substrates for the oxidative half-reaction in AP constructs. In a recent study, Reisner and Kuehnelt discussed the use of biomass lignocellulose for H₂ production at room temperature and light irradiation in a photoreforming process.^{144, 145} Although the reduction half-reaction generates H₂ cleanly as a fuel, the biomass oxidation half-reaction is unselective and predominantly yields CO₂, which also presents opportunities to develop new processes to obtain more value-added feedstocks from non-food biomass.^{144, 145} For example, Sun and coworkers reported the oxidation of furfuryl alcohol and 5-hydroxymethylfurfural (HMF) coupled with a H₂ evolution half-reaction using earth-abundant electrocatalysts.^{146, 147} The reaction was conducted under strongly alkaline conditions and carboxylate products were obtained, of which 2,5-furandicarboxylic acid is a promising replacement for terephthalic acid in polyamides, polyurethanes, and polyesters.¹⁴⁷ Their subsequent visible-light induced oxidative valorization of furfuryl alcohol and HMF over Ni

Fig. 11 (a) C-C bond cleavage of lignin model compound A, ¹³C-labeled A-¹³C2, and the two deuterium labeled A-D1 and A-D2. The corresponding labeled products verify the absence of isotope scrambling, indicating that the benzylic alcohol oxidation to ketone did not occur prior or after the C-C bond cleavage. (b) The ¹H and ²H (insets) NMR spectra aiding our assignment of reaction products after C-C bond cleavage: A before (I) and after 24 h irradiation (II); A-¹³C2 after 24 h irradiation (III); A-D1 after 24 h irradiation (IV); and A-D2 after 24 h irradiation (V). The data have been adapted from reference 149.

decorated ultrathin CdS nanosheets in neutral water resulted in selective formation of value-added aldehyde or acid products, depending on the reaction conditions.¹⁴⁸ Unfortunately, aldehydes appeared to inhibit the Ni/CdS catalyst, which led to incomplete conversion of HMF.¹⁴⁸ Nonetheless, their work is an important demonstration that biomass derived feedstocks can be upgraded to value-added aldehydes or acids, which are commonly used in the pharmaceutical and fragrance industries. This oxidative half-reaction produces more valuable solar chemicals than O₂ from H₂O.

Bearing the versatile plug-and-play concept in mind, our group has been exploring the oxidation of non-food biomass lignin as another half-reaction in an AP system. Lignin, a sizable constituent of non-food biomass, is especially attractive since it represents one of the only renewable sources of aromatic compounds on Earth. However, although much effort has been devoted to the valorization of lignin into fuels through thermal and microbial reactions, majority of the valuable aromatic units and functional groups are destroyed. In our work on lignin model compounds, we have uncovered a unique V^V photocatalyst (Fig. 10a) that is able to induce a highly selective and unprecedented C-C bond scission in aliphatic alcohols under visible light irradiation and ambient, atmospheric conditions (Fig. 11 – 13).¹⁴⁹ Surprisingly, the more common alcohol oxidation to ketones is not competitive since it occurs only at temperatures exceeding 80 °C.¹⁴⁹

A number of representative lignin models were successfully screened for reactivity.¹⁴⁹ Notably, the exceptionally mild and regioselective C-C bond cleavage produced valuable aryl aldehyde and formate compounds in moderate to high yields.¹⁴⁹ Detailed mechanistic studies and product analyses were conducted with the aid of ²H and ¹³C isotope labeling experiments, which revealed no isotope scrambling and alluded to an unusual pathway for direct C-

C bond cleavage after photoexcitation (Fig. 11).¹⁴⁹ Our experimental work was further supported by computational density functional theory (DFT) calculations which suggested that the V^V photocatalyst was indeed capable of absorbing visible light via LMCT and trigger the unexpected C-C bond cleavage adjacent to the alcohol group (**TS1** in Fig. 12).¹⁴⁹ This produced an aldehyde, while the resulting radical went on to react with O₂ (**Int1** and **Int2** in Fig. 12) and eventually transformed into an oxygenated product such as formate.¹⁴⁹

Following our initial success on the photooxidative C-C bond activation in aliphatic alcohols, we have improved upon our original design and developed a library of modified V^V photocatalysts (Fig. 10b).¹⁵⁰ By introducing strong electron-withdrawing groups such as NO₂ and F at specific locations of the ligand where there is spin density on the HOMO (Fig. 10a), we were able to stabilize the HOMO energy level and increase the oxidative potential of the V^V photocatalyst.¹⁵⁰ As anticipated, one of the more strongly oxidizing photocatalysts reacted up to 7 times faster than our earlier complex, although excessive substitution led to retarded reaction rates, likely because the catalyst was not as readily re-oxidized by O₂.¹⁵⁰

Furthermore, although our photocatalysts showed good reactivity with most of our original lignin model compounds, phenolic groups were not well tolerated. We surmised that the formate product in the lignin model compounds may have hydrolyzed into guaiacol, which may have poisoned the catalyst at high conversions. Thus, we prepared a new lignin model compound with one extra carbon so that the secondary hydrolysis product would be benzyl alcohol instead of a phenol (Fig. 13b).¹⁵⁰ Remarkably, this new substrate underwent C-C bond cleavage between 2.5 – 17 times faster, depending on the V^V complex used,

Fig. 12 Proposed mechanism based on DFT calculations for our unusual C-C bond cleavage adjacent to the alcohol group without isotope scrambling, after LMCT photoexcitation of the V^V catalyst. Note that the activation barrier of **TS1** is merely 6.1 kcal mol⁻¹, compared to a barrier of 20.2 kcal mol⁻¹ for hydrogen atom abstraction from the benzylic position. The data have been adapted from reference 149.

Fig. 13 Reaction scheme (top) and kinetics data (bottom) of the C-C bond cleavage reaction in our original lignin model compound (a) and the new lignin model compound with an extra carbon atom (b). The kinetics plots are depicted with substrate concentration decay over time with different catalysts at 10 mol% loading (bottom left) and only the fastest catalyst at different loading levels (bottom right). The figures are adapted from reference 150.

supporting our hypothesis that one of the catalyst deactivation pathways is through secondary phenolic product inhibition.¹⁵⁰ Using thorough kinetics measurements (Fig. 13) and DFT studies, we were able to identify the fastest catalyst in our library, as well as gain insights into the choice of the optimal substrates for our unique C-C bond cleavage reactivity.¹⁵⁰

Although these studies are currently examined independently from the reductive half-reaction, we believe that this unusual C-C bond activation reaction is a suitable oxidative half-reaction candidate to plug into an AP system that would valorize biomass and other organic substrates to produce solar chemicals. Moreover, we hope to highlight its value for future research on LMCT induced C-C bond activation by photocatalysts composed of earth-abundant elements, and also broaden the scope of feedstocks suitable for integrated AP.

5. Outlook and concluding remarks

Solar water splitting has often been considered as a “holy grail” of AP due to its significance and parallel to natural photosynthesis in generating solar fuels from abundant water. AP offers the versatility to store sunlight in energetic molecules without the need for batteries, allowing us to separate when we collect and use renewable energy. If it can

be produced in a clean fashion in the reductive half-reaction from a sustainable, renewable, and abundant resource, H₂ can be readily utilized as a fuel. It can be stored and used on demand, and reverts back to water upon oxidation, closing the cycle of generation and utilization of green energy. The water oxidation half-reaction, however, usually produces O₂, which has only limited commercial value and can even form reactive oxygen species to damage the catalysts. Hence, a modular system that combines the desired reductive and oxidative half-reactions will be more flexible than a traditional water splitting process, which produces only H₂ and O₂.

In this feature article, we have highlighted the progress of our small but growing community in creating plug-and-play AP systems that can be used for the simultaneous production of solar fuels and solar chemicals in the two redox half-reactions. Such AP systems provide a number of benefits over water splitting. The oxidative process can potentially yield solar chemicals more valuable than O₂ such as halogens (industrial disinfectants), polymer feedstocks, aromatic and carbonyl functionalized compounds, and even pharmaceutical precursors. Furthermore, through our experimental work on improving the catalyst design by kinetics measurements, understanding the deactivation pathways, and identifying the vital functional groups in substrates, we have demonstrated that a mild and selective C-C bond activation in alcohols is a promising candidate for the oxidative half-reaction in AP. The fundamental studies have also paved the way for us to explore even more substrates and develop reusable catalysts. In addition, plug-and-play systems can be easier to develop and assemble. The main components of the system, including the light harvester, charge mediator, reduction catalyst, and oxidation catalyst can all be independently optimized before being integrated into the desired AP system. It will also be amenable to high throughput screening and modern data analysis methods. We anticipate that our conceptual model will augment the field with numerous opportunities in each of the functional aspects discussed, and hope that AP will be a bedrock of the future global sustainable energy solution.
