DOI: 10.1039/b000000x

Position- and orientation-controllable micropatterned ZnO/TiO₂ nanostructures with different morphologies have been fabricated using a novel and versatile superhydrophilic/superhydrophobic template. Scanning electron microscopy, optical microscopy, electron probe microanalysis and X-ray diffraction were systematically used to confirm the successful fabrication of the patterns and to characterize the structure and morphology. The selective growth of ordered ZnO nanostructured patterns on the TiO₂ nanotube surface employs a simple photocatalytic lithography technique with mild reaction conditions and in the absence of seeds and noble metal catalysts. The photoelectrical properties of the micropatterned ZnO/TiO₂ nanocomposites with unique heterojunction structure and different density and orientation of the ZnO crystals were also investigated. It is expected that this novel micropatterned technique based on the superhydrophilic/superhydrophobic template will become a powerful tool for fabricating various types of micropatterned nanomaterials and devices.

1. Introduction

Wettability of solid surfaces is one of the important properties that is governed by both the chemical composition and geometrical structure.^{1–4} Extreme wettability contrast (*i.e.* superhydrophilic/superhydrophobic) is a potentially powerful and economical approach to precisely construct nanostructures in aqueous solution. So far, only few reports on the fabrication and application of superhydrophilic/superhydrophobic patterning are available.^{5–9}

The deposition of ZnO nanostructures on a variety of substrates has attracted great attention due to its wide applications in sensing,^{10–12} optoelectronics^{13–15} and light emitting displays.^{16–18} Moreover, the controlled growth and synthesis of ZnO nanostructures on large scale is of particular importance in making new types of functional semiconductor devices and constructing micro- and nano-electromechanical systems (MEMS/NEMS).^{19–21} To control the resulting ZnO properties, an appropriate choice of synthesis and processing parameters plays a crucial role. Over the past few years, nanostructured ZnO periodic patterns have been created using seed layers,^{22,23} noble metal catalysts,^{24–26} patterned photoresists²⁷ and mold replication on smooth substrates.^{28,29} For example, Sun *et al.*²³ reported ZnO patterns using a hydrothermal approach assisted by spin-coating a ZnO seed layer. Yu and co-authors²⁶ successfully fabricated ordered

ZnO nanorod patterns on Si substrates through an Au catalytic vapor–liquid–solid process. Although they could provide precise position control, the involvement of complicated equipment and the strict requirements of the processing steps and environment have limited the practical usefulness in fabricating large areas of nanostructures in a high-throughput fashion. Therefore, the extension of a mild, low-cost bottom-up synthetic route that does not require vacuum technologies and seed/catalyst layers is highly desired. Recently, Song *et al.*^{30,31} developed a novel biomimetic approach for selective assembly of nanostructured semiconductor patterned films onto flexible polymer substrates treated with a simple UV exposure carboxylation process.

In this paper, we propose a novel seed/catalyst-free patterning process based on an extreme wettability contrast (superhydrophilic/superhydrophobic) template to fabricate position- and orientation-controlled large-scale ZnO nanorod patterns on TiO₂ nanotube array surfaces. Specifically, our strategy involves the formation of enhanced wettability contrast template first, followed by selective growth of ZnO nanostructures in the superhydrophilic regions. In the superhydrophobic regions, the growth is suppressed. This special template can be utilized to generate different nanostructured ZnO patterns with clearly defined edges. Our approach, in contrast to others, offers several advantages including extraordinary versatility (fabrication performed under ambient conditions), low cost, and non-reliance on potentially harmful metal catalyst (or seeding layer). Hence, this novel method is particularly useful and promising in fabricating functional nanostructures on a large scale.

2. Experimental

2.1 Preparation of superhydrophilic/superhydrophobic pattern

Titanium ($\geq 99.5\%$) sheets were anodized with a Pt counter electrode in 0.5 wt% HF electrolyte solution under 20 V for

20 min to fabricate TiO₂ nanotube arrays, as reported in more detail previously.^{32–35} The as-prepared amorphous TiO₂ nanotube films were calcined at 450 °C for 2 h to form the crystalline anatase phase. The nanotube structures were then treated in a methanolic solution of hydrolyzed 1 wt% 1*H*,1*H*,2*H*,2*H*-perfluorooctyltriethoxysilane (PTES, Degussa Co., Ltd.) for 1 h, and subsequently heated at 140 °C for 1 h to remove residual solvent. Superhydrophobic patterns were obtained by selective exposure to a 200 W high-pressure mercury lamp (maximum intensity at 365 nm, 100 mW cm^{–2}) under ambient conditions for 20 min through a photomask placed on its surface. The light irradiation photocatalytically cleaves the hydrophobic fluoroalkyl chain of PTES,^{7,36} turning the rough surface from superhydrophobic to superhydrophilic.

2.2 ZnO nanorod patterning

The vertical ZnO nanorod arrays were prepared by an electric field assisted deposition method.³⁰ Precursor solutions were prepared by dissolving zinc nitrate hexahydrate (Zn(NO₃)₂·6H₂O, ≥ 99%) and hexamethylenetetramine (C₆H₁₂N₄, ≥ 99%) in doubly deionized water. The concentration of zinc and amine were fixed at 5 mM. A piece of Pt plate acted as the counter electrode. During ZnO deposition the resistive voltage may drop across the cell preventing potential-dependent deposition and thus a constant current density of 0.25 mA cm^{–2} at 90 °C was used for 3 min. The deposited sample was then picked up from the container and thoroughly rinsed with distilled water and dried in air. For a comparative study, ZnO nanostructured crystal patterned samples were also investigated by direct liquid phase deposition without the presence of electric field under identical experimental conditions (the patterning surface placed upward).

2.3 Material characterizations

The morphology and composition of the patterns were observed by a field-emission scanning electron microscope (FESEM, LEO-1530, Germany) combined with energy dispersive spectroscopy (EDS). The chemical element distribution was measured by an electron probe microanalyzer (EPMA, JEOL JXA-8100, Japan). The crystallinity of the samples before and after annealing treatment was measured using an X-ray diffractometer with Cu-Kα radiation (XRD, Phillips X'pert-PRO PW3040). The water contact angle was measured with an optical contact angle meter system (Dataphysics, OCA-20) at ambient temperature. The water droplets used for the static contact angle and sliding angle measurements were 4 and 7 mg, respectively. The values reported are the average of five drops per sample at different locations. For fluorescence experiments, the obtained patterns were stained with fluorescein sodium, and observed by a Karl Zeiss fluorescence microscope (Axioskop2, MAT). The patterned TiO₂ nanotube array samples were observed by optical microscopy (Eclipse E600, Nikon). Atom force microscopy (AFM) in tapping mode was performed on a Nanoscope IIIa (Digital Instrument Co., USA). For confocal microscopy, a Leica TCS SP5 with a He/Ne laser and fluotar objective, was used to investigate the morphology of the materials at

micrometer scale. These measurements produced three-dimensional maps of the surfaces.

2.4 Photocurrent measurements

The photocurrent action spectra were measured in a home-built two-electrode configuration experimental system, where the as-synthesized ZnO/TiO₂ nanocomposite film served as the working electrode with an active area of about 1 cm². A platinum wire was used as the counter electrode in the supporting electrolyte of 0.1 M aqueous Na₂SO₄ solution. A 150-W Xe lamp with a monochromator was used as the light source. The generated photocurrent signal was collected by using a lock-in amplifier synchronized with a light chopper. All measurements were controlled automatically by a microcomputer.

3. Results and discussion

The fabrication process involves three main steps, as schematically illustrated in Fig. 1. First, a superhydrophobic titania nanotube array surface was fabricated using an electrochemical anodizing method and a self-assembling monolayer (SAM) technique (step 1 in Fig. 1). Second, the superhydrophilic/superhydrophobic micropattern was transferred to the substrate by a previously established photocatalytic lithography technique using a photomask. Finally, ZnO nanostructured crystals were grown on the titania micropattern in the absence or presence of an electric fields. Details of each step are described in the Experimental section.

Fig. 2(a) shows a typical FESEM image of the substrate before electrochemical anodization. The surface of the titanium substrate was relatively smooth, with features of polished ridges, grooves and pits at the micron scale. After anodization, some unevenness was observed, shallow cavities as large as several micrometers in diameter were present on the surface of the sample (Fig. 2(b)). This is probably due to the anisotropic oxidation of the underlying Ti grains.^{37–39} From the high magnification image (Fig. 2(c)), it can be seen that vertically oriented TiO₂ nanotubes with inner diameter of approximately 80 nm covered the entire surface including the shallow polygonal micropits. The side view image shows

Fig. 1 Schematic illustration of the fabrication procedure of ZnO nanocrystal micropatterns based on a superhydrophilic/superhydrophobic template. First, superhydrophobic TiO₂ nanotube array films were formed on the titanium substrate (step 1). Then the superhydrophilic/superhydrophobic micropatterns were prepared by photocatalytic lithography with a photomask (step 2). Finally, the ZnO nanostructures were grown on the patterned template in the absence or presence of an electric field (step 3).

that the self-assembled layers of the TiO₂ nanotubes were open at the top and closed at the bottom with thickness about 350 nm (inset of Fig. 2(c)). The inset of Fig. 2(b) shows the intrinsic contact angle (CA) on the as-prepared vertically aligned TiO₂ nanotube surface and its corresponding PTES modified surface is nearly 0° (superhydrophilic) and 156° (superhydrophobic), respectively. Moreover, the sliding angle of a 7 mg water droplet on the PTES modified TiO₂ nanotube sample is $12.1 \pm 1.9^\circ$, indicating a medium adhesive strength of water droplets on such vertical nanostructures due to its typical “line-contact” behavior.⁴ However, the CA for the “flat” TiO₂ surface and its corresponding PTES modified sample is about 46° (hydrophilic) and 115° (hydrophobic), respectively. From these results, we know the top surface of the vertically aligned nanotubes has an amplification effect to make hydrophilic and hydrophobic surfaces become superhydrophilic and superhydrophobic, respectively. After UV irradiation for 30 min, the water CA on the TiO₂ nanotube film and “flat” TiO₂ film decreased to 0° and 26°, as a consequence of the photocatalytic activity of TiO₂ films.^{40,41} Water droplets can quickly spread and wet the as-grown vertically aligned TiO₂ nanotube film due to the side penetration of liquid by capillary forces in the special tubular structure. Moreover, after the UV irradiation, the sample showed hydrophobic character once again when it was treated with PTES. Therefore the surface can be reversibly switched between superhydrophobic and superhydrophilic by alternating SAM and UV photocatalysis on the rough TiO₂ nanotube arrays (shown in Fig. 2(d)). Compared with the large wettability contrast on this type of rough surface (larger than 150°), the wettability of a “flat” TiO₂ film can only be reversibly changed within the small range between 26 and 115°.

The fabrication of superhydrophilic/superhydrophobic micropatterns (Fig. 3(a)) on TiO₂ nanotube array films is described in the Experimental section. To verify the resulting micropatterns, fluorescein sodium was used as a probe to label the patterning surface. Fig. 3(b) shows the fluorescent micrograph of the resultant superhydrophilic/superhydrophobic micropatterns on TiO₂ nanotube films. As shown, geometrically identical bright green superhydrophilic regions (microdots with a diameter of 50 μm) and dark superhydrophobic regions transferred well from the photomask to form a well-defined pattern. The UV irradiated regions become superhydrophilic owing to the photocatalytic cleavage of PTES molecules and the enhanced roughness of the nanotube structures, while the non-irradiated parts remain superhydrophobic without any change. Since the difference of the water CA between the irradiated and non-irradiated regions is larger than 150°, liquid containing fluorescent probe selectively and uniformly resides only on the superhydrophilic areas, not the neighboring superhydrophobic regions. Therefore, a clearly defined fluorescent pattern in line with the dimensions of the photomask could be obtained through wettability contrast. In addition, such a surface micropattern could potentially be used in erasable and rewritable mode due to the efficient photocatalytic activity of this special TiO₂ nanostructure.

On the basis of this patterning template, we exploited the extremely large wettability contrast between superhydrophilic regions and the adjacent superhydrophobic areas to precisely

induce ZnO nanostructure deposition by several techniques. Fig. 3(c) shows the optical micrograph of the as-prepared ZnO/TiO₂ micropattern (by electric field assisted deposition for 3 min) based on superhydrophobic/superhydrophilic micropatterns on the TiO₂ nanotube array surface. It can be seen that the patterning shape of the ZnO crystals is the same as the template used.

Fig. 4 shows representative top-view FESEM images of the ZnO/TiO₂ micropatterns by liquid-phase deposition after different times. After growth for 30 min (Fig. 4(a) and (b)), the nucleation and growth of ZnO crystals with various morphologies and sizes (nanoparticles and nanorods) are sparsely dispersed within the predefined superhydrophilic regions. In the superhydrophobic regions, the nanotube structure is retained with its original morphology due to the indirect contact with the solution and the effective protection by the PTES monolayer. Upon further increase in the deposition time to 90 min (Fig. 4(c) and (d)), it was observed that ZnO nanorods were the predominant structural features. The average diameter of the grown ZnO nanorods increases greatly to about 400–800 nm in diameter and 3–5 μm in length, which may be due to lower nucleation rate and higher growing space for ZnO nanorods. The superhydrophilic microdots are almost covered with randomly lying ZnO nanorods. Moreover, there are different growth orientations and some connections into adjacent nanorods. It is of interest to note that a two-dimensional (2D) pattern with smaller density of randomly packed ZnO nanorods, instead of the 3D pattern consisted of well-aligned vertical nanorods, which were confined and grown within the superhydrophilic regions.

For practical application of thin film devices, the position- and orientation-control of ZnO nanorods are very important because they directly relate to their physical and chemical performances.^{42,43} In order to precisely control the spatial orientation of the ZnO nanostructures, we developed a new technique which is able to make the ZnO nanorods grow along the vertically aligned titania nanotubes rather by disordered deposition on the titania nanotube array surface. In this technique, resistance discrepancy was adopted to make the entrance of the tubes more conductive than the bottom of the tubes, to induce the epitaxial growth with spatial organization of uniform ZnO nanorods along the direction of the nanotubes. The quasi-perpendicular ZnO nanorods nucleate and grow uniformly and selectively throughout the superhydrophilic regions of the TiO₂ nanotube surface by electric field assisted deposition at 90 °C for 3 min, while no nanorods are observed in the superhydrophobic regions (Fig. 5(a) and (b)). The EDS spectra also reveal that the presence of Zn, Ti and O elements on the superhydrophilic regions, while the elemental components in the superhydrophobic areas are only Ti and O. The inset of Fig. 5(b) shows the hexagonal end facet of a vertically aligned ZnO nanorod with a diameter about 100–150 nm growing on top of the TiO₂ nanotube array surface. Therefore, the density, size and orientation of ZnO nanorods are very sensitive to the presence of electric fields.

A 3D AFM profile image (Fig. 5(c)) shows that the microscopic structure of the ZnO crystal deposition consisted in dense column arrays, which are induced and directed by the wettability template. The thickness of vertical ZnO nanorod

Reversible surface wettability on a “flat” TiO_2 film and rough nanotube TiO_2 film by alternating SAM and UV photocatalysis (d). The inset of (b) shows the shape of a water drop on the PTES-modified and UV-irradiated TiO_2 nanotube array film. The inset of (c) shows the side view of a TiO_2 nanotube array film.

Fig. 3 Optical micrographs of the as-prepared superhydrophilic/superhydrophobic microtemplate (a), fluorescence microscopic image of the fluorescein probe on the corresponding superhydrophilic/superhydrophobic microtemplate (b), and the resulting patterned microarrays of ZnO/TiO_2 nanostructures (c).

film is in the range of 800–900 nm. Furthermore, the three-dimensional confocal microscopy image (Fig. 5(d)) also shows that the growth of the ZnO nanorod pattern is identical with the superhydrophilic/superhydrophobic template. Moreover, the Zn and O element distribution mappings measured by EPMA provide convincing evidence that the ZnO nanorods were only present in the superhydrophilic regions (Fig. 6(a) and (b)). The reason for the success of large area fabrication of well-defined patterns with clear boundaries is that the superhydrophobic regions covered by the PTES monolayers were isolated from the aqueous solution during the deposition. Fig. 6(c) and (d), shows the line-scan signal intensity profiles of zinc and oxygen elements across the pattern obtained after electric field assisted deposition for 3 min. It can be seen that both the line profiling of zinc and oxygen signal intensity increased greatly within the superhydrophilic regions. This

suggests that most or all of the TiO_2 surface areas corresponding to the superhydrophilic regions were homogeneously covered by ZnO nanorods, while the superhydrophobic regions remained almost unchanged due to the suppression by the air trapped in the nanotubes and the crevices between nanotubes.⁴ This image agrees well with the observed results by FESEM. The slight deviation of the detected signal intensity was due to analytical errors caused by the rough nanostructures.

Fig. 7 shows the XRD patterns of the ZnO/TiO_2 coupled nanocomposites, which provide further insight into the crystal structure and orientation of the assembled ZnO nanocrystals. The as-prepared TiO_2 nanotube array film on metal Ti substrate before annealing did not show any TiO_2 peaks indicating the crystal structure of the TiO_2 was amorphous (Fig. 7(a)). For the TiO_2 nanotube films calcined at 450 °C for

Fig. 4 SEM images of the patterned ZnO nanostructured micropatterns by liquid phase deposition at 90 °C for different times: (a, b) 30 min; (c, d) 90 min.

Fig. 5 Typical SEM images of (a, b) the vertically aligned ZnO nanorods selectively grown on superhydrophilic patterning regions by the developed electric field assisted deposition technique at 90 °C for 3 min. 3D AFM image of the ZnO/TiO₂ micropattern (c). (b) Shows the higher magnified SEM image of a ZnO nanorod with hexagonal end facet.

2 h the new peaks can be well indexed as phase-pure anatase TiO₂ (Fig. 7(b)). The ZnO/TiO₂ film obtained by direct liquid phase deposition (Fig. 7(c)) shows only a weak diffraction peak for ZnO since the ZnO deposition rate was very low and the quantity was not sufficient to give a strong signal. In the case of the prepared ZnO nanorods by electric field assisted deposition (Fig. 7(d)), three obviously characteristic peaks

($2\theta = 31.77, 34.42$ and 36.25°), marked by their Miller indices ((100), (002) and (101)) were observed. This reveals that the resultant ZnO nanorods were in the wurtzite phase (JCPDS no. 36-1451). Compared to the TiO₂ mono-component nanomaterials, the coupled nanocomposites indeed consisted of both anatase TiO₂ and wurtzite ZnO after annealing, which is clearly shown in the XRD pattern. Furthermore, the (002)

Fig. 6 The chemical composition of area-scan and line-scan signal intensity mapping of Zn (a, c) and O (b, d) of the vertical ZnO nanorod micropattern on a TiO₂ nanotube array surface after electric field assisted deposition for 3 min.

diffraction peak of well-oriented vertical ZnO nanorods induced and directed by the perpendicular nanotube array structure using the electric field assisted technique exhibit greater intensity than that of the randomly packed ZnO nanorods by regular liquid phase deposition, indicating the highly preferential growth of the ZnO nanorods along the *c* axis and perpendicularly to the substrate surface (see the inset in Fig. 7). These XRD results agreed with the SEM observation and demonstrate that the orientation-controlled growth of ZnO nanostructures can be effectively realized by use of a predefined extreme wettability contrast template on a TiO₂ nanotube array surface.

In order to examine the structure-specific properties of the nanostructured ZnO/TiO₂ hybrid materials, measurements of the photocurrent action spectra were performed in a home-built photoelectrochemical measurement system. The results of photocurrent actions for all the samples, which were collected in the range from 250 to 500 nm are shown in Fig. 8. As shown, the as-prepared amorphous TiO₂ nanotube sample showed no photocurrent response, while the annealed TiO₂ and ZnO/TiO₂ nanocomposites exhibited obvious photocurrent responses with maximum wavelength at 320 and 340 nm, respectively, which were blue-shifted from the band gap of bulk TiO₂ (387 nm, 3.2 eV) and ZnO (368 nm, 3.37 eV) due to the quantum confinement effect.⁴⁴ In the case of the prepared coupled ZnO/TiO₂ nanocomposites, the photocurrent was found to be largely enhanced with higher photocurrent intensities than that of the compact TiO₂ film obtained directly by thermal oxidation at 450 °C for 2 h. Furthermore, because of the synergistic effect, the photocurrent spectrum of the coupled ZnO/TiO₂ nanocomposite was slightly blue-shifted from that of the ZnO nanorods. Interestingly, the photoelectrodes of the ZnO/TiO₂ nanocomposites showed a smaller photocurrent spectrum (300–400 nm) than that of the monocomponent TiO₂ nanomaterials (275–400 nm). Moreover, all the ZnO/TiO₂ coupled heterojunctions exhibited

Fig. 7 XRD patterns of the as-prepared TiO₂ nanotube film (a), TiO₂ nanotubes (b) and ZnO/TiO₂ nanocomposites prepared by direct liquid phase deposition (c) and electric field assisted deposition (d) upon sintering in air at 450 °C for 2 h. A, Z and T represent anatase TiO₂, ZnO and Ti substrate, respectively. The inset image shows an enlarged view of the ZnO peaks.

moderate photocurrent intensity between that of the compact TiO₂ film and the TiO₂ nanotube film. It is also found that the photocurrent intensities of the resultant coupled ZnO/TiO₂ nanocomposite decreased with an increase of the deposition time whether an electric field was present or absent. The beneficial influence of a lower degree of ZnO deposition agrees with the report by Kim⁴⁵ and Yoon *et al.*⁴⁶ Also, the generated photocurrent of the well-oriented perpendicular ZnO nanorod electrode prepared by electric field assisted deposition was much higher than that of the randomly distributed ZnO nanorod electrode. This may be attributed to that the vertical and more even ZnO nanorod film on the TiO₂ nanotubes

Fig. 8 Photocurrent spectra of (a) amorphous TiO_2 nanotube electrode, (b) compact TiO_2 film electrode, (c) anatase TiO_2 nanotube electrode, (d) vertically aligned ZnO nanorod micropattern on TiO_2 nanotube surface (1.5 min), (e) vertically aligned ZnO nanorod micropattern on TiO_2 nanotube surface (3 min), (f) randomly lying ZnO nanorod micropattern on TiO_2 nanotube surface (30 min) and (g) randomly lying ZnO nanorod micropattern on TiO_2 nanotube surface (90 min).

allows for more efficient electron transfer and greater surface area at the intimate ZnO/ TiO_2 heterojunctions. Light harvesting and charge transfer within such 3D organized junctions with well aligned vertical ZnO morphology are enhanced. These results demonstrate the importance of optimizing coupled nanostructured electrodes in an orderly orientation. Indeed, the photocurrent response of the micropatterned ZnO/ TiO_2 composite depends on many structural factors, which should be further studied.

The advantages of this simple approach lie in its generality and high selectivity for solution-based deposition without the presence of noble metal catalyst, and it can be easily extended to other coupled nanostructured materials of any arbitrary shape. In addition, with such versatile assembly of functional nanomaterials based on superhydrophilic/superhydrophobic templates, it is possible to open a new avenue to micro- and nanodevice fabrication and enable applications in a wide variety of fields such as microfluidic devices,⁴⁷ biotechnology,^{48,49} water harvesting surfaces,⁵⁰ and site-selective deposition templates,^{51,52} etc.

4. Conclusion

In summary, we have demonstrated a successful application using a superhydrophilic/superhydrophobic template for position- and orientation-controlled growth of ZnO nanorods on TiO_2 nanotube array surfaces. Spatial organization of ZnO crystals over large areas can be achieved with excellent selectivity. The micropatterned ZnO/ TiO_2 nanocomposite showed a better photocurrent response due to its unique heterojunction structure. These novel nanostructure patterning strategies based on wettability contrast can also be expanded to direct the deposition of other nanostructured materials

from aqueous solution, which opens up avenues for potential applications in nanomaterials and technologies.
