KEYWORDS Two-layer gold surface, 2D heterospectral correlation spectroscopy, redox protein, cytochrome c, surface-enhanced Raman spectroscopy, surface-enhanced infrared absorption spectroscopy

ABSTRACT: The heme protein cytochrome c adsorbed to a two-layer gold surface modified with a self-assembled monolayer of 2-mercaptoethanol was analyzed using a two-dimensional (2D) heterospectral correlation analysis that combined surface-enhanced infrared absorption spectroscopy (SEIRAS) and surface-enhanced Raman spectroscopy (SERS). Stepwise increasing electric potentials were applied to alter the redox state of the protein and to induce conformational changes within the protein backbone. We demonstrate herein that 2D heterospectral correlation analysis is a particularly suitable and useful technique for the study of heme containing proteins as the two spectroscopies address different portions of the protein. Thus, by correlating SERS and SEIRAS data in a two-dimensional plot, we can obtain a deeper understanding of the conformational changes occurring during the electron transfer process - at the redox center as well as in the supporting protein backbone. The correlation analyses is complemented by molecular dynamics calculations to explore the intra-molecular interactions.

1. INTRODUCTION

Cytochrome c (cyt c) is an important heme protein that functions as an electron carrier within the electron transport chain. As a model system, it has attracted intensive research attention using different characterization techniques.¹ Electrochemistry has been successfully used as an important tool to study the functionality of the protein by providing an external potential to mimic the electron transfer process.² Unfortunately, electrochemistry provides little structural information. X-ray crystallography and NMR spectroscopy, on the other hand, are well-known
structural characterization techniques that have been applied to the cytochrome c system.\(^3\) Although very useful, they are not applicable for dynamic studies such as the ones encountered here due to the lack of temporal resolution. Moreover, it is not possible for all the proteins to form a well-ordered crystal. Spectroscopic methods also have been applied by several groups; UV-Vis reflectance spectroscopy was used to study the electron transfer rate \(^4\), and Edmiston et al. utilized fluorescence spectroscopy to determine the molecular orientation when the protein was bound to a surface.\(^5\) Second-order harmonic spectroscopy has been used to determine the adsorption kinetics.\(^6\) Quartz crystal microbalance (QCM) and surface plasmon resonance (SPR) have also been used to study the electron transfer process of cytochrome c on gold electrode modified with different self-assembled monolayers.\(^7\)

Vibrational spectroscopy is very powerful for characterization of the hydrogen bonding pattern and secondary structure of proteins and polypeptides. Ataka et al. studied cytochrome c on different self-assembled monolayer (SAM) structures using SEIRAS difference spectroscopy.\(^8\) Spiro et al. attempted the complete assignment of cytochrome c through isotope labeling.\(^9\) A complicating factor though is that cyt c possesses the unique characteristic that its backbone is strongly infrared active but hardly detected using Raman spectroscopy, whereas the heme center is Raman active but gives rise to a very weak infrared signal. Thus, the protein structure or conformational change cannot be entirely described by either technique alone, which sometimes has led to ambiguous conclusions that are still a topic of debate. Hence both techniques, Raman and infrared are complementary techniques as they reveal information of both the protein backbone and the redox center.

Two-dimensional (2D) correlation spectroscopy was first developed by Noda in 1989 and has triggered many research efforts thereafter.\(^10\) It utilizes a mathematical method to plot the series
of dynamic spectra generated by external perturbation (temperature, time, potential, etc.) on a two-dimensional scale, hence generating two types of plots, namely, synchronous and asynchronous. This technique is advantageous because it can resolve overlapping peaks and provide information about the sequence of dipole reorientation/conformational change etc. For example, Wu et al. utilized 2D IR spectroscopy to study the thermal unfolding of ribonuclease A upon reduction,\textsuperscript{11} and Ozaki et al. used 2D Raman spectroscopy to study the molecular interaction between chemical components in pharmaceutical tablets.\textsuperscript{12} Heterospectral 2D IR-Raman analysis also has been investigated by Noda et al \textsuperscript{13} for the study of N-methylacetamide. However, most of the 2D correlation studies have been used to explore the same structural segment of the molecule. To the best of our knowledge, the present work is the first attempt to apply 2D heterospectral correlation analysis to address different parts of the target protein, which is possible because of the special characteristics of cytochrome c stated above. Hetero 2D would allow us to correlate the changes in the infrared and Raman spectra. Additionally, by combining IR and Raman spectroscopy, the sequential pattern of the conformational changes in cyt c can be probed by applying the sequential rules of 2D correlation spectra. Molecular dynamics calculations are also performed to examine the interaction between the functional units probed by the hetero 2D correlation, and to reveal details of intra-molecular interactions.

2. EXPERIMENTAL SECTION

2.1 Materials. Gold(III) chloride trihydrate (AuCl\textsubscript{3}·3H\textsubscript{2}O, 99.999\%), hydroxylamine hydrochloride (NH\textsubscript{2}OH HCl, 99\%), cytochrome c from bovine heart, sodium perchlorate, 3-aminopropyltrimethoxysilane (APTMS), and 2-mercaptoethanol were purchased from Sigma-
Aldrich. Dipotassium phosphate was purchased from Merck, Darmstadt. All chemicals were used without further purification.

2.2 Preparation of the two-layer gold film on a silicon surface. The samples were prepared using the optimal conditions described in our previous work\textsuperscript{14}. Briefly, a 30 nm gold film was deposited by electrothermal evaporation onto an ATR-crystal after a thorough rinse with ethanol and sonication. To grow the second gold layer, the substrate was immersed in 50 mL of an aqueous solution containing 0.4 mM hydroxylamine hydrochloride to which 500 μL of an aqueous solution of gold (III) chloride trihydrate (0.3 mM) was added. After 2 min, an equivalent aliquot of the AuCl\textsubscript{3} solution was added. This process was repeated 5 times such that the sample remained in the growth solution for a total of 10 min. The sample was removed from the growth solution, rinsed with water, and dried in a stream of nitrogen. Thereafter, the sample was immersed in an aqueous solution of 2-mercaptoethanol (ME) (1 mM) for 15 minutes and then rinsed with water. Subsequently, cyt c was adsorbed for 60 min using a solution of cc (0.35 mM) in PBS buffer (20 mM K\textsubscript{2}HPO\textsubscript{4} and 10 mM NaClO\textsubscript{4}, pH 7).

2.3 Spectroelectrochemical measurements. All electrochemical measurements were recorded in a homemade liquid cell using an Autolab instrument (PGSTAT302) equipped with an ECD module amplifier for low currents, an ADC750 module for rapid-scan measurements, and a SCANGEN module for analog potential scanning (Eco Chemie, B.V., Utrecht, Netherlands). All measurements were collected using a three-electrode configuration with the gold film as the working electrode, an Ag/AgCl, KCl\textsubscript{sat} reference and a platinum wire as the counter electrode. All electrode potentials are reported relative to the standard hydrogen electrode (SHE).

The IR measurements were performed as described previously\textsuperscript{14}. The spectroelectrochemical cell was mounted on top of a trapezoidal silicon ATR-crystal required for a single reflection in
the attenuated total reflection spectroscopy (ATR) mode. The IR beam of the FTIR spectrometer
(VERTEX 70 FTIR spectrometer, Bruker, Karlsruhe, Germany) was coupled to a prism at an
angle of incidence $\Theta = 60^\circ$. The total reflected beam IR intensity was measured using a
photovoltaic MCT (mercury cadmium telluride) detector. For the static measurements, the mirror
velocity was 120 kHz, the resolution was 4 cm$^{-1}$, and 1000 scans were collected for one spectrum
during a measurement time of 10 min. All spectra were measured using parallel polarized light.
The spectra were analyzed using the software package OPUS 6.5 (Bruker, Karlsruhe).

The Raman experiments were performed on the combined system of WITec confocal Raman
microscope using the 532 nm line of a Nd:YAG laser with circular polarization. It corresponds to
the Q electronic transition of the heme. The laser beam was coupled to a confocal Raman
microscope (Alpha 300, WITec) equipped with a water immersion objective (Nikon 60*, NA =
1.0, WD = 2.0). Thus, the laser beam was focused and the scattered light was filtered by an edge
filter and guided to the spectrometer (UHTS 300, WITec) by a 600 grooves/mm grating to
provide the spectral resolution. The recorded spectrum was imaged onto a thermoelectrically
cooled EMCCD detector (WITec). The Raman spectra were acquired using a 15 s integration
time with a laser power density of $2.6\times10^6$ W/cm$^2$ with spot size of $\sim1$ μm$^2$. The SERS spectra
were analyzed using the software packages WITec control 1.54 and WITec project 2.06.

2.4 2D Correlation Calculations. The synchronous and asynchronous 2D plots of the
infrared, Raman, and heterospectral correlations were calculated using the software 2D Shige ©
Shigeaki Morita, Kwansei-Gakuin University, 2004-2005. The calculated data was re-plotted in
Origin for better visualization. The color bar shows the different intensities of the 2D correlation
peaks, which indicates the extent of correlation between x and y variables.
2.5 Molecular Dynamics (MD). The simulations were based on the crystal structure of the oxidized form of bovine heart cytochrome c (PDB code: 2B4Z) using the GROMOS11\textsuperscript{15} software and the GROMOS 54A7\textsuperscript{16} force field. The crystal structure was modified by removing the covalent bond between the heme and His18 and Met80, while adding the thioether bridges to the heme vinyl groups through Cys14 and Cys17. The simulations of the reduced form used the same initial structure but different charge parameters on the heme. The GROMOS++\textsuperscript{17} package was used for simulation analysis. The dihedral based secondary structure classification was based on the work of Hollingsworth \textit{et. al.}\textsuperscript{18} The precise simulation settings are described in the supporting information.

3. RESULTS AND DISCUSSION

3.1 General considerations. Cytochrome c is a small size (12,000 Daltons) highly conserved protein that is found in viruses, plants humans, etc. Its primary structure is made up of 100 amino acids, though many higher order organisms consist of 104 amino acids. It is an important component in the electron transport chain, and that is loosely bound to the inner membrane of mitochondria. It consists of 5 α-helices, 2 beta strands, and some turn structures, which can be detected by infrared spectroscopy and assigned to specific portions of the protein.\textsuperscript{8}

In our previous work, a two-layer gold surface was used to enhance the SEIRAS signal of adsorbed cyt c, and we found that a growth period of 10 min for the second gold layer provided optimal conditions.\textsuperscript{14} Identical surfaces were prepared for both the SEIRAS and SERS to ensure similar experimental conditions. As shown in Figure S1 (supporting information), the atomic force microscopy images clearly show that the initial surface is smooth, with an average roughness of 1.9 nm. After 10 minutes, the surface became rough due to the growth of a second
layer of gold nanoparticles into islands and the average surface roughness increased to 6.9 nm. Such two layer gold surface has been utilized before by our group in a 2D correlation study of cytochrome c oxidase and cytochrome c.\textsuperscript{19} The motivation of the present work is to advance the understanding of the interaction between the heme group and the surrounding protein backbone upon changing the electrode potential.

The two-layer gold surface was modified with 2-Mercaptoethanol (ME) prior to adsorption of cyt c. Hydroxyl-terminated SAM has been suggested to weakly affect the conformational characteristics of cyt c upon adsorption.\textsuperscript{8} Moreover, cyclic voltammetry data shows that cyt c is successfully adsorbed onto the two-layer gold surface. The oxidation peak (cathodic peak) at 280 mV and the reduction peak (anodic peak) at 203 mV agree well with the previously reported values\textsuperscript{19b} (Figure S2).

The infrared difference spectra of cyt c have been studied before using this same methodology and surface architecture (Figure S3).\textsuperscript{19b} Detailed assignments can be found in Table S2. The main infrared peaks and the corresponding assignments discussed in the text are summarized in Table 1. As the potential increases, the peaks at 1552 cm\textsuperscript{-1} and 1658 cm\textsuperscript{-1} increase in intensity, and one
additional peak appears at 1672 cm\(^{-1}\). These peaks are characteristic for oxidized cyt c and correspond to the amide II band of a type III \(\beta\) -turn, the amide I band of a type II \(\beta\) turn and/or \(\alpha\)-helix and type III \(\beta\)-turn, respectively. Simultaneously, the peak at 1692 cm\(^{-1}\), corresponding to the amide I band of the type III \(\beta\)-turn (reduced state), decreases in intensity with increasing electrode potential (Figure S3) and possesses a sigmoid appearance (Figure S4.) Taken together, the sigmoid appearance of the 1692 cm\(^{-1}\) intensity (Figure S4) clearly indicate that cyt c undergoes a change from the reduced state to the oxidized state.

For the SERS measurement, a 532 nm laser is used as the excitation source to match the Q electronic transition of the heme instead of the B band. This is preferred since gold surface is used to achieve maximum signal enhancement. The SERS spectra show no obvious changes until +50 mV vs. SHE, as can be observed in Figure 1. As the potential increased further, all of the
peaks decrease in intensity except for the ν_{10} peak at 1621 cm\(^{-1}\), which increases. The ν_{10} peak corresponds to the C-C asymmetric stretching mode, ν(C_α−C_m)_{asym}. A sigmoid behavior is also observed for the 1364 cm\(^{-1}\) peak intensity, as shown in Figure 1 (inset). Again this sigmoid curve shows that the redox transition can be followed by the spectral intensity change, Note that unspecific re-orientation of the protein on the surface won’t give such sigmoid behavior.\(^{19b}\) For detailed Raman peak assignment we refer to the work by Spiro et al\(^9\) and Table S1, which are in good agreement with the peaks found in our experiment. The selected peaks and their corresponding assignment are shown in Table 2 as will be discussed in relation to the 2D correlation plots.

Figure 1. Evolution of the SERS active peaks surface with potential (from -100 mV - 500 mV vs. SHE) for cytochrome c adsorbed to the 2-mercaptoethanol SAM-modified two-layer gold substrate. The black arrows are used to label the peaks that increase or decrease in intensities as the potential increases. (Inset: The sigmoid behavior of intensity change of Raman peak at 1364 cm\(^{-1}\)).
3.2 2D IR. Overlapping peaks arising from different functional groups make it difficult to analyze the infrared peaks of cyt c, thus hindering accurate band assignments and reliable determination of the conformational changes of the protein. Second-derivative or Fourier deconvolution analyses have been applied to address this problem, but some of the findings and conclusions do not agree with the results from X-ray crystallography and NMR studies. Reaction-induced infrared difference spectroscopy also has been developed both for the bulk and the SAM layer of cyt c, and the ability to enhance the spectral resolution was demonstrated using an enzymatic reaction. The concept of the difference spectra suits the basis of 2D correlation spectroscopy, which also utilizes an external perturbation (light, voltage, etc.) to generate dynamic spectra for analysis. The use of 2D correlation spectroscopy spreads the spectrum in the second dimension and facilitates the deconvolution of overlapping peaks. Thus it can help enhance the spectral resolution. Although vibrational features of different molecular origin may contribute in a similar manner to the spectra in the static case, they may behave differently (either delayed or accelerated) in the case of a dynamic change, which can be distinguished by 2D correlation. Thus, 2D correlation is an effective tool for deconvoluting overlapping peaks.
**Figure 2.** Synchronous (A) and asynchronous (B) 2D IR correlation plots from a SEIRAS analysis of cyt c adsorbed to a two-layer gold surface.

The synchronous and asynchronous 2D infrared correlation plots of cyt c were calculated using the 2D Shige© software package from the series of 1D IR spectra generated with stepwise increased potentials from −100 mV to +500 mV (Figure 2). The peaks that undergo changes in intensity result in correlation peaks in the 2D plots, whereas the peaks that remain constant result in no or very small correlation peaks. The autopeaks along the diagonal are all positive in a synchronous 2D IR plot (Figure 2A) and reveal the major peaks of the 1D infrared spectra. However, these peaks exhibit different degrees of intensity change during the potential increase. In the synchronous 2D IR plot, the intensity of the autopeak at 1692 cm⁻¹ is more pronounced than that at 1658 cm⁻¹ (Figure 2A), suggesting that the sequence of peptide groups responsible for the 1692 cm⁻¹ autopeak are influenced to a greater extent by the applied potential than those responsible for the 1658 cm⁻¹ autopeak. By examining the IR peak assignment⁸, it leads to the
conclusion that the amide I band of the type II β-turn and/or α helix (1658 cm⁻¹) and the amide I band of the type III β-turn (1692 cm⁻¹) originate from different regions of the protein backbone. Thus, different regions of the protein backbone can be probed by changing the applied potential, as revealed by the synchronous 2D IR plot.

Cross peaks in the synchronous 2D IR plot are also indicative of modes with coupled or related origin. For example, the strong correlation peak at (1552 cm⁻¹, 1692 cm⁻¹) indicates that the spectral features at these two positions may be related, and most likely belong to the same segments of the protein backbone – the type III β-turn, Table 1. The negative peak sign (dark blue), however, suggests that the peak intensities at the two positions change in different directions. The fact that one of them belongs to the reduced state and the other one the oxidized state clearly suggests that the redox transition was successfully recorded.

The asynchronous plot (Figure 2B) provides additional useful information about the sequential relationship between the changes in intensity of peaks with different spectral origins, thus making it useful for peak deconvolution. The spectra in Figure 2B do not include any autpeaks, which is a distinct characteristic feature of an asynchronous 2D spectrum. We observed a strong negative cross peak at (1658 cm⁻¹, 1692 cm⁻¹) and a strong positive cross peak at (1692 cm⁻¹, 1658 cm⁻¹). By applying Noda’s rules for analyzing 2D correlation spectra, the peptide groups corresponding to the amino acids in the type II β-turn and/or α helix (represented by the peak at 1658 cm⁻¹) change their conformation before those in the type III β-turn (represented by the peak at 1692 cm⁻¹). Since the signal change of the amino residues represented by the IR peak 1692 cm⁻¹ occurred after those represented by the IR peak 1658 cm⁻¹, the amino acids 14-19 and 67-70 may re-orient to the surface first followed by those at positions 32-38 (Table 1). We conclude by
comparing existing literature\textsuperscript{8} observations with our findings that the changes seen in the 2D IR plots can be attributed to conformational changes within the protein backbone.

### 3.3 2D Raman

Prior to the heterospectral 2D correlation analysis, the 2D Raman correlation spectra were calculated from the series of 1D Raman spectra at increasing potentials to probe how the Raman active heme group responds. The synchronous 2D Raman correlation plot is shown in Figure 3. In addition to the positive autopeaks, most of the cross peaks were also positive, which indicates that all of the peak intensities decreases during the potential increase except for the peak at 1621 cm\textsuperscript{-1}, which resulted in a negative peak in the 2D spectrum and, therefore, increased in intensity. This synchronous 2D Raman correlation agrees well with the observation from the 1D Raman spectra, Figure 1.

According to the peak assignment by Spiro et al.,\textsuperscript{9} the Raman peaks at 1397 cm\textsuperscript{-1} and 1587 cm\textsuperscript{-1} correspond to vibrational modes of the pyrrole quarter ring and the C–C bond, respectively (Table 2). The pyrrole quarter ring is located next to the iron center of the heme, whereas the C–C bond is located further away from the heme center. As can be observed from the synchronous 2D Raman correlation spectrum, the peak intensity of the 1587 cm\textsuperscript{-1} autopeak is much more pronounced than that of the autopeak at 1397 cm\textsuperscript{-1}. This observation indicates that the $\nu(C_\alpha-C_m)_{\text{asym}}$ mode (corresponding to the peak at 1587 cm\textsuperscript{-1}) has a stronger correlation to the change in potential than the $\nu$(pyrrole quarter ring) has (corresponding to the peak at 1397 cm\textsuperscript{-1}). This is in agreement with literature\textsuperscript{25} and our MD simulation suggesting that the heme unit is prone to re-orient (bend upward or downward) with the applied potential. Hence the $\nu(C_\alpha-C_m)_{\text{asym}}$ mode is, as expected, more sensitive to conformational changes than the $\nu$(pyrrole quarter ring) mode. The two peripheral propionic acid groups, that are a part of the heme structure, also can establish strong interactions with neighboring amino acid residues via
hydrogen bond/electrostatic interaction. Thus different modes respond differently to applied potential because of changes in the local environment.

The asynchronous 2D Raman correlation plot, in contrast, does not exhibit significant peaks. Instead, the signals appear within the noise level (Figure S5). The lack of significant features is most likely due to the fact that the corresponding peaks may exhibit frequency shifts in addition to pure intensity changes. This induces noise in the 2D spectra. Thus the asynchronous correlation analysis is typically more sensitive to noise than the synchronous analysis was.24

According to Noda10c, the asynchronous correlation intensity vanishes when all reorientations of the two dipole-momentum transitions occur in phase with the external perturbation. Hence, all Raman-active regions of cyt c are expected to react at the same rate following a potential perturbation due to the rigid structure of the heme center. This is consistent with the conclusion that the bonding distance between the six ligands with the heme center iron ion doesn’t change during the redox process, as revealed by recent X-ray investigation.21,26

![Figure 3. Synchronous 2D Raman correlation plot from the SERS spectra of cyt c on gold.](image)

**Figure 3.** Synchronous 2D Raman correlation plot from the SERS spectra of cyt c on gold.

3.4 **Hetero 2D.** Thus far, only autologous IR- or Raman-active modes have been correlated. We introduce also a heterospectral correlation analysis of the infrared and Raman spectra
representing different parts of the protein. Such 2D spectra combining these two complementary techniques could serve as a visualization aid to describe more complete conformational change of cyt c during the redox process. The synchronous and asynchronous 2D heterospectral correlation plots are again calculated using the 2D Shige© software and the result is shown in Figure 4. The infrared frequency is chosen as the x-axis, and the Raman shift as the y-axis, which makes the coordinate system as (IR peak position, Raman peak position) in the hetero 2D plot. These 2D heterospectral correlation plots are no longer symmetrical about the diagonal line, which is in contrast to the autologous IR-IR or Raman-Raman 2D spectra. Hence, all peaks had to be interpreted as cross correlation peaks.

The synchronous 2D heterospectral correlation plot, Fig. 4A, shows that the infrared peak at 1658 cm\(^{-1}\) forms strong positive peaks with the main Raman peaks, and that the strongest peaks are formed with the Raman peaks at 1314 cm\(^{-1}\) and 1587 cm\(^{-1}\). There are also positive peaks formed under the IR peak at 1552 cm\(^{-1}\) with these Raman peaks. For the correlation under the peak at 1692 cm\(^{-1}\), two negative peaks are observed, which are not on the same scale as the positive peaks.
As mentioned before, an examination of the band assignments suggests that the IR peaks at 1692 cm\(^{-1}\) and 1552 cm\(^{-1}\) both can be attributed to the type III beta-turn, with the 1692 cm\(^{-1}\) peak corresponding to the reduced state and the 1552 cm\(^{-1}\) peak to the oxidized state. During the potential change from -100 mV to +500 mV vs. SHE, cyt c undergoes a redox change from the fully reduced state to the fully oxidized state, which is reflected well in the synchronous 2D heterospectral correlation plot by the negative sign of the correlation peak. The IR peak at 1658 cm\(^{-1}\) corresponding to the type II beta-turn and/or \(\alpha\) helix in the oxidized state involves the residues 32-38. These residues can interact directly with the propionate groups of cyt c and
thereby exhibit a strong correlation with the heme during the redox process. The different intensities of the correlation peaks also indicated a large extent of reorientation.

Interestingly, the 1692 cm\(^{-1}\) peak, which corresponds to the amino acids near His 18 that is ligated to the heme iron, resulted in smaller correlation peaks than the peak at 1658 cm\(^{-1}\) did. A possible interpretation of these data could be that the strong coupling between His 18 and the heme prevents the two moieties from changing configuration and/or reorient. In contrast, the residues associated with the propionate groups have more freedom to move, thus inducing more reorientation during the redox process. The correlation peaks between the IR peak 1692 cm\(^{-1}\) (corresponds to the amino acids 14-19, including the His-18) with the Raman peaks are either absent or very weak. On the other hand, the correlation peaks between IR peak 1658 cm\(^{-1}\) are strong in intensity and show different peak sign as compared to the peaks under IR peak 1692 cm\(^{-1}\). This indicates a different coupling mechanism between the contributing amino acid residues and the heme center.

The asynchronous 2D heterospectral correlation plot is shown in Figure 4B. We assume that the general rules developed by Noda are valid for all kinds of 2D correlation methods, and can be applied to our data as described in the following. The sign of the asynchronous 2D heterospectral correlation peak is positive at (1692 cm\(^{-1}\), 1587 cm\(^{-1}\)), whereas the sign of the peaks at the same position in the synchronous hetero 2D plot indicate that the sequential relationship for this set of data has to be inversed\(^{10c}\). Thus, by applying the Noda’s rules to the hetero 2D plots, the residues represented by the IR peak at 1692 cm\(^{-1}\) would reorient after the heme, which is represented by the Raman peak at 1587 cm\(^{-1}\). This analysis allows us to visualize the dynamics of the redox process of cyt c as follows: the heme moiety first undergoes a conformational change, because it
directly coordinates to the iron ion involved in the redox process. This is followed by a reorientation of the His 18 residue that is ligated to the heme iron.

We also observed two additional peaks in the asynchronous 2D heterospectral correlation plot at (1692 cm\(^{-1}\), 1364 cm\(^{-1}\)) and (1692 cm\(^{-1}\), 1397 cm\(^{-1}\)), which are absent in the synchronous 2D heterospectral correlation plot. Based on the peak assignment (Table S1), the Raman peaks at 1364 cm\(^{-1}\) and 1397 cm\(^{-1}\) correspond to the stretching modes of \(\nu(\text{Pyr half-ring})_{\text{sym}}\) and \(\nu(\text{Pyr quarter-ring})\), respectively. According to these findings we propose that, upon oxidation the heme undergoes a vibrational change that reflects a change in the distance between the pyrrole group and His 18. Additional to the described findings, we could show with the help of MD calculations, that there is stronger coupling between the heme structure and the protein backbone shown in Figure S6.

The broad synchronous peak at (1658 cm\(^{-1}\), 1314 cm\(^{-1}\)) is split into three separate peaks in the asynchronous plot at 1624 cm\(^{-1}\), 1658 cm\(^{-1}\), and 1672 cm\(^{-1}\), respectively, because they are of different origins and display different sequential interactions with the applied external potential. Again, these IR peaks correspond to the amide I bands of the extended \(\beta\)-strand, the type II \(\beta\)-turn and/or \(\alpha\) helix and the type III \(\beta\)-turn, respectively. A similar splitting behavior can be observed with the Raman peak 1587 cm\(^{-1}\), but not with the Raman peaks 1364 cm\(^{-1}\) and 1397 cm\(^{-1}\). A closer examination of the Raman vibrational mode assignments (shown in Table 2) reveals that the peaks showing splitting (1314 cm\(^{-1}\) and 1587 cm\(^{-1}\)) correspond to the pyrrole side chain, while those showing no splitting (1364 cm\(^{-1}\) and 1397 cm\(^{-1}\)) correspond to either pyrrole half-ring or quarter-ring vibrations, respectively. This clearly shows that, asynchronous 2D heterospectral correlation analysis can be used to deconvolute overlapping peaks originating from segments of different rigidity, molecular environment, etc.
The potential dependent response for amino acid 14-19 and 67-70, as represented by the infrared peak 1692 cm\(^{-1}\), is out of phase of the heme center, as shown from the strong hetero asynchronous correlation between IR peak 1692 cm\(^{-1}\) and all the Raman peaks. The same conclusions can be drawn from the strong correlation between the Raman peaks at 1314 and 1587 cm\(^{-1}\) with all the infrared peaks in the amide I region. This indicates that the conformation change of these two Raman vibrational modes are out of phase with those represented by the infrared amide I peaks. The amide II peak at 1552 cm\(^{-1}\) is assigned to the same amino acids as the amide I peak at 1692 cm\(^{-1}\), but they represent different redox states. That’s why they observed same degree of asynchronous change, but in different directions.

The correlation peaks between the IR peak 1692 cm\(^{-1}\) and the Raman peaks, which are weak or absent from the synchronous spectra, increase their intensity in the asynchronous spectra. On the other hand, the correlation peaks between the IR peak 1658 cm\(^{-1}\) and the Raman peaks, which are strong and positive in the synchronous spectra, disappear or become weak in the asynchronous spectra. This could indicate a change of the bond angle between the two axial ligands His-18 and Met-80, and also the position shift of the propionate group, since the different correlation may indicate the change of relative positions. This is also consistent with the findings by XRD and NMR.\(^{21, 26, 28}\)

3.5 Molecular Dynamics. To confirm our observations and conclusions, molecular dynamics simulations were also performed. Because there are no prominent changes seen in the overall secondary structure associated with the oxidation, the secondary structure dynamics for each residue are examined. The amount of time each residue spent in a particular secondary structure class was determined for both the oxidized and reduced forms. Those residues for which this time varied by at least 5% (or less if they were close to a previously monitored residue) are
collected in Table S3. The residue assignments from the 2D heterospectral correlation spectroscopic analysis are consistent with the residues that experienced a change in their secondary structure assignments or interaction dynamics with the heme propionates as shown in Figure 5.

The simulations show a decreased amount of time spent in the β-turn type III structure, including residues 14-17 (-7%) and 67-69 (-7%), during oxidation of the protein, which agrees well with the assignment peaks at 1692 and 1552 cm⁻¹ (Table S2). An unassigned region of residues 52-55 took up the β-turn type III at an increased proportion (+10%) as shown in Table S3. This region was also identified to change upon oxidation in horse heart cyt c. In our simulations it is associated with propionate hydrogen bonding/electrostatic interaction (Table S4), rather than with direct interaction through His18 or Met80, as the other two regions are. This is also reflected in the asynchronous hetero 2D plot shown in Figure 4B, that the helix structure differ from the beta turn structure in molecular environment; hence they can be distinguished by combing the hetero 2D analysis and MD simulation.

The IR peak at 1658 cm⁻¹ is assigned to β-turn type II and/or α helix structure, and to the two consecutive turns at residues 32-35 and 35-38. During the MD simulations both turns are observed, but the change in secondary structure is very small (3 and 6 %) upon oxidation, which is in good agreement with NMR and X-ray observations. On the other hand, the turns changed H-bonding dynamics with the heme (Arg38), and established important hydrogen bond interactions with the regions 14-19, and 21-23 (Asn31).
Figure 5. (A) Amino acids with changed secondary structure dynamics (orange) and heme hydrogen bonding (purple) based on MD simulations. (B) Amino acids in the amide I region detected using 2D SEIRAS and associated with the IR peaks at 1658 cm\(^{-1}\) (blue) 1692 cm\(^{-1}\) (red) and 1624 cm\(^{-1}\) (yellow). Green parts are unmarked, and the heme is shown in grey, oxygen and nitrogen atoms are colored red and blue, respectively.

Additionally, the distance of the heme and His18 was also monitored in the different oxidation states (Figure S6). Although the average distance changes only slightly, the smaller charge of the reduced heme center allowed for more fluctuations, in good agreement with the stronger coupling observed in the hetero 2D correlation analysis.

4. CONCLUSIONS

We have successfully performed a 2D correlation analysis upon changing the redox state of cyt c adsorbed on a two-layer gold surface. 2D infrared correlation and 2D Raman correlation spectroscopies were performed to enhance spectral resolution and to provide a deeper understanding of the sequential changes occurring in the various portions of the protein.

Specifically, we have performed three types of correlation analysis, namely, autologous IR vs. IR, Raman vs. Raman and heterologous IR vs. Raman. Our data indicate that different segments
of the protein respond differently to change in the electrode potential and reoriented sequentially. For example, it is found that the heme groups reoriented and changed conformation/interactions prior to the rest of the protein backbone. Some peaks that are not readily observed in the 1D spectra can be distinguished using a 2D correlation analysis. Peaks arising from different spectral origins or different molecular environments can be differentiated by their dynamic change under an external perturbation. Thus, the oxidation of cytochrome c can be readily monitored using 2D correlation analysis. There is also a good agreement between the results of the 2D analysis and the molecular dynamics simulations, e.g. the distance study between the His18 and the heme is reflected in the 2D correlation spectra to reveal the conformation change of the protein.

These findings are remarkable because they show a clear fragmentation of sequential order, which indicates that the conformational changes induced by the oxidation occurred at different rates for different parts of the protein backbone. The example of a well-studied system, such as cytochrome c, has effectively demonstrated the potential of 2D heterospectral correlation spectroscopy for further applications on more complex membrane redox proteins.
