(Received 2 August 2010; published 21 December 2010)

We improve the steady-state ab initio laser theory (SALT) of Türeci et al. by expressing its fundamental self-consistent equation in a basis set of threshold constant flux states that contains the exact threshold lasing mode. For cavities with nonuniform index and/or nonuniform gain, the new basis set allows the steady-state lasing properties to be computed with much greater efficiency. This formulation of the SALT can be solved in the single-pole approximation, which gives the intensities and thresholds, including the effects of nonlinear hole-burning interactions to all orders, with negligible computational effort. The approximation yields a number of analytic predictions, including a “gain-clamping” transition at which strong modal interactions suppress all higher modes. We show that the single-pole approximation agrees well with exact SALT calculations, particularly for high-Q cavities. Within this range of validity, it provides an extraordinarily efficient technique for modeling realistic and complex lasers.

I. INTRODUCTION

The foundation of our understanding of lasers is semiclassical laser theory, in which the gain medium is treated quantum-mechanically and the electromagnetic fields are treated classically. The pioneering work of Haken [1] and Lamb [2] showed that the Maxwell-Bloch (MB) equations, in which the gain medium is modeled by an ensemble of two-level atoms, successfully describe the principal properties of lasers, including modal thresholds, lasing frequencies, output power, the structure of the electromagnetic fields inside and outside of the laser cavity, as well as dynamical effects such as relaxation oscillations and mode, phase, and frequency locking. The only properties that cannot be obtained from the semiclassical theory are those that depend on quantum fluctuations of the electromagnetic field, such as the laser linewidth, amplified spontaneous emission, and photon statistics.

Because the MB equations are coupled nonlinear equations in space and time, few purely analytic results could be obtained from the theory. Those obtained generally relied on a number of drastic approximations: The mode structure was assumed to be simple (e.g., spatially uniform or low-order Gaussian modes), the openness of the laser system was handled either through adding phenomenological damping to closed-cavity modes or by approximating the lasing modes as quasimodes of the passive cavity, and the nonlinear modal interactions were either ignored or simplified by solving the equations near threshold. Where such approximations could not be employed, reliable theoretical results could only be obtained from brute force time-domain simulations of the MB equations [3] or their multilevel generalizations.

The past 2 decades have seen the emergence of novel laser systems based on complex resonators, driven by advances in microfabrication and motivated by applications to integrated on-chip optics, as well as by basic scientific interest. Examples are vertical-cavity surface-emitting lasers [4], microdisks [5,6], spiral [7] and (wave-chaotic) deformed disk lasers [8–11], photonic crystal lasers [12,13], and random lasers [14,15]. The analytical theory existing at the time was not readily applicable to these complex systems; the random laser, in particular, poses a difficult conceptual challenge as
(SALT) [27]. The term \textit{ab initio} refers to the fact that the only inputs are the dielectric function for the passive cavity and a few parameters to describe the gain medium. The SALT method thus bridges the gap between oversimplified analytical approaches and time-domain simulations. Unlike the former, it describes laser cavities of arbitrary complexity and openness, making no assumptions about the nature of the lasing modes or frequencies or the proximity to threshold. Unlike the latter, it yields direct semianalytic insights into the lasing solutions. Furthermore, the SALT method is in general much more computationally efficient than time-domain simulations; due to the elimination of the time variable, it allows for calculations that are impractical in the time domain due to limitations in computer speed or memory.

In the present work, we present a significant improvement to the SALT method by introducing a new basis set that always contains the exact threshold lasing solution. The properties of the new basis functions allow us to compute the lasing solutions above threshold more efficiently than before. They also allow us to derive an approximation to the full SALT for high-\( Q \) lasing cavities, which we term the single-pole-approximation SALT (SPA-SALT), which is valid well above threshold in contrast to the HS theory [21]. The SPA-SALT approximation yields solutions with negligible computational effort, once the threshold lasing properties are known. From this simplified theory, we derive several analytic results for the lasing behavior above threshold, including relatively simple formulas for the thresholds of higher lasing modes. These results hold to infinite order in the nonlinear modal interactions and are hence quantitatively reliable. Strikingly, these results predict a “gain-clamping” transition, in which higher modes are prevented from turning on at any pump, despite the nonuniformity of the lasing modes.

The remainder of this article is organized as follows. In Sec. II, we review the previous formulation of the SALT and the solution method based on the basis set of constant-flux states and describe the limitations imposed by this basis set. In Sec. III, we present the new basis set and the formulation of the SALT in terms of this basis and examine the efficiency of the new solution method. In Sec. IV, we derive the simplified form of the SALT equations arising from the “single-pole approximation” (SPA-SALT). We then solve these equations analytically and demonstrate good agreement with the exact SALT solutions. In the appendices we derive the power approximation” (SPA-SALT). We then solve these equations.

Here, we restrict the fields to one dimension (1D) or to the transverse magnetic (TM) polarization in 2D so the electric and polarization fields are scalars (the generalization to TE modes in 2D is straightforward). Their positive-frequency components are \( E^+(\vec{r},t) \) and \( P^+(\vec{r},t) \); in these equations, we have made use of the rotating-wave approximation (RWA). Note that we have not used the standard slowly varying envelope approximation, employed in most treatments to eliminate second time derivatives; this approximation gives no benefit in the SALT approach and is unnecessary [17]. We have taken the speed of light in a vacuum \( c \) to be unity; wave vector and frequency will be distinguished by the context. \( D(\vec{r},t) \) is the population inversion, and \( D_0(\vec{r}) \) is the pump; \( k_\parallel \) is the frequency of the gain center, \( \gamma_\perp \) is the gain width (polarization dephasing rate), \( \gamma_1 \) is the population relaxation rate, \( g \) is the dipole matrix element, and \( \epsilon(\vec{r}) \) is the cavity dielectric function, which in general is complex and includes the material absorption inside the cavity. Arbitrary cavity elements, such as mirrors, can be represented by an appropriate choice of \( \epsilon(\vec{r}) \), although we will focus on dielectric cavities in our examples below. We assume that the \( E^+ \) and \( P^+ \) fields obey a multimode ansatz

\[
E^+(\vec{r},t) = \sum_{\mu=1}^N \Psi_\mu(\vec{r}) e^{-i\omega_\mu t},
\]

\[
P^+(\vec{r},t) = \sum_{\mu=1}^N P_\mu(\vec{r}) e^{-i\omega_\mu t},
\]

where the indices \( \mu = 1, 2, \ldots, N \) label the different lasing modes. The total number of modes, \( N \), is not given but increases in unit steps from zero as we increase the pump strength \( D_0 \). The values of \( D_0 \) at which each step occurs are the (interacting) modal thresholds, to be determined self-consistently from the theory. The real numbers \( k_\parallel \) are the lasing frequencies of the modes, which will also be determined self-consistently.

We insert the ansatz (4) into Eqs. (1)–(3) and employ the stationary inversion approximation \( \bar{D} = 0 \). The result is a set of coupled nonlinear differential equations, which are the fundamental equations of the SALT [28]:

\[
\nabla^2 E^+ - \epsilon(\vec{r}) \nabla^2 \bar{E}^+ = 4\pi \bar{P}^+, \tag{1}
\]

\[
P^+ = -(k_\parallel - i\gamma_\perp) P^+ + \frac{g^2}{\hbar} E^+ D, \tag{2}
\]

\[
\dot{D} = \gamma_1(D_0 - D) - \frac{2}{\hbar} [E^+(P^+)^* - P^+(E^+)^*]. \tag{3}
\]

\( \Psi \) and \( D \) are now dimensionless, measured in their natural units \( e_c = \hbar \sqrt{\gamma_1 \gamma_\perp} / (2g) \) and \( d_c = \hbar \gamma_1 / (4\pi g^2) \), and \( \Gamma_\perp = \gamma_1^2 / [g^2 + (k_\parallel - k_\perp)^2] \) is the Lorentzian gain curve evaluated at frequency \( k_\parallel \). Equation (5) is simply a wave equation for the electric field mode \( \Psi_\mu \), with an effective dielectric function consisting of both the “passive” contribution \( \epsilon(\vec{r}) \) and an “active” contribution from the gain medium. The latter is frequency dependent and has both a real part and a negative (amplifying) imaginary part. It also includes infinite-order nonlinear “hole-burning” modal interactions, seen in the \( |\Psi_\mu|^2 \) dependence of (6). In addition, we make the key requirement that \( \Psi_\mu \) must be purely out-going outside the cavity; it is

\[
\nabla^2 \psi + \left[ \epsilon(\vec{r}) + \frac{\gamma_\perp D(\vec{r})}{k_\parallel - k_\perp + i\gamma_\perp} \right] k_\perp^2 \Psi_\mu(\vec{r}) = 0, \tag{5}
\]

\[
D(\vec{r}) = D_0(\vec{r}) \left[ 1 + \sum_{\nu=1}^N \Gamma_\nu |\Psi_\nu(\vec{r})|^2 \right]^{-1}. \tag{6}
\]
this condition that makes the problem non-Hermitian. It is worth noting that the stationary inversion approximation is not needed until at least two modes are above threshold, so (6) is exact for single-mode lasing up to and including the second threshold (aside from the well-obeyed RWA).

Let us define a finite cavity region $C$, such that

$$D_0(\vec{r}) = 0 \quad \text{and} \quad \epsilon_\mu(\vec{r}) = n_\mu^2, \quad \vec{r} \notin C. \quad (7)$$

Although we call $C$ the “cavity” region, $\epsilon_\mu(\vec{r})$ need not be discontinuous at its boundary. The theory applies, for instance, to random lasers lacking any well-defined boundary [25,26]. For our purposes, $C$ simply defines a surface of last scattering (or last amplification), a region outside of which there is no dielectric nor gain material to affect the free propagation of waves.

We write the external pump as

$$D_0(\vec{r}) = D_0 F(\vec{r}), \quad \vec{r} \in C, \quad (8)$$

where $D_0$ is the “pump strength” and $F(\vec{r})$ a fixed “pump profile,” both real quantities. The simplest case, $F(\vec{r}) = 1$, corresponds to uniform pumping within the cavity. In general $F(\vec{r})$ need not be uniform, e.g., if the pump is a finite laser spot or the gain material is distributed unevenly.

The lasing equation now becomes

$$\left\{ \nabla^2 + \left[ \epsilon_\mu(\vec{r}) + \gamma_\mu D_0 F(\vec{r}) \right] k_\mu^2 \right\} \Psi_\mu(\vec{r}) = 0 \quad (9)$$

in which $h(\vec{r}) \equiv \sum_\mu \Gamma_\mu |\Psi_\mu(\vec{r})|^2$ represents the spatial hole burning effect. Here we have introduced the abbreviation

$$\gamma_\mu \equiv \gamma_\mu / (k_\mu - k_\mu + i\gamma_\mu). \quad (10)$$

Previous treatments of the SALT [16,17,25,26] proceeded by inverting Eq. (9) via the Green’s function to yield an equivalent integral equation, but for our purposes it is more convenient to retain the differential form.

**B. Modal output power**

Using Eq. (9) we can determine the unknown lasing frequencies $k_\mu$ and mode fields $\Psi_\mu(\vec{r})$. From these quantities, all other properties associated with the semiclassical steady state can be derived. For instance, an important quantity not treated explicitly in earlier versions of the SALT is the time-averaged modal output power $P_\mu$. This can be obtained in two ways. First, it can be calculated from the asymptotic outgoing fields, which are directly calculated in some numerical approaches [25]. Alternatively, the Poynting flux through a loop enclosing a 2D cavity can be converted into an area integral, which gives the convenient expression:

$$P_\mu = \frac{k_\mu}{2\pi} \int_C d^2r \left\{ \frac{\Gamma_\mu D_0 F(\vec{r})}{1 + h(\vec{r})} \right\} |\Psi_\mu(\vec{r})|^2. \quad (11)$$

A more detailed discussion and derivation of the modal output power is given in Appendix A.

**C. Threshold lasing modes and constant-flux states**

The lasing equation (9) always admits the trivial solution $\Psi = 0$. Below the first lasing threshold, this is the only self-consistent solution. As $D_0$ is gradually increased from zero, at some value there emerges an additional self-consistent solution, consisting of a single lasing mode $\Psi_\mu(\vec{r})$. Right at threshold, this mode has infinitesimal amplitude, $\Psi_\mu(\vec{r}) \to 0$. Hence, the hole-burning term $h(\vec{r})$ is negligible and (9) reduces to a linear equation:

$$\left\{ \nabla^2 + \left[ \epsilon_\mu(\vec{r}) + \gamma_\mu D_0 F(\vec{r}) \right] k_\mu^2 \right\} \Psi_\mu(\vec{r}) = 0. \quad (12)$$

Note that the second term in parentheses, which we will refer to as $\epsilon_\mu(\vec{r})$, is simply the linear amplifying dielectric function of the pumped gain medium. As shown in the following sections, this equation has a discrete set of nontrivial solutions, specified by the two positive real numbers, $(D_0^2, k_\mu^2)$, the threshold values of the pump and lasing frequency. Each of these solutions would be a perfectly valid lasing mode at threshold for that specific pump value, assuming that all other modes are suppressed for some reason. We refer to this set of functions with their corresponding frequencies as the threshold lasing modes (TLMs). They can be thought of as the noninteracting modes, i.e., the modes that would turn on in the absence of modal interactions, and their thresholds $D_0^\mu$ are the noninteracting thresholds.

There is another interesting interpretation of the TLMs. The linear wave equation (12) defines an electromagnetic scattering matrix which gives the out-going wave amplitudes in terms of the incident wave amplitudes. The outgoing-only boundary condition implies that the relevant solutions correspond to poles of this $S$ matrix, i.e., eigenvectors with eigenvalue tending to infinity. When $D_0 = 0$, these poles are just the resonances of the passive cavity defined by the wave equation

$$[\nabla^2 + \epsilon_\mu(\vec{r})] \psi(\vec{r}) = 0, \quad (13)$$

with an out-going boundary condition. If the cavity is lossless and $D_0 = 0$, then the corresponding $S$ matrix is unitary; otherwise it is not flux conserving. For any cavity in equilibrium (i.e., lossless or absorbing) these solutions exist only for complex $k$, with $\text{Im}(k) < 0$; hence, outside $C$, these modes grow exponentially toward infinity, which means that they are not physically realizable [16]. When $D_0 > 0$, the dielectric function in (12) is not merely the passive $\epsilon_\mu(\vec{r})$ but includes a complex nonequilibrium amplifying contribution $\epsilon_\mu(\vec{r})$ from the gain medium, whose effect is to move the poles “upward” toward the real axis (see Fig. 1). The noninteracting thresholds associated with the TLMs are the values of the pump that move the pole corresponding to each resonance onto the real axis, making it a physically possible threshold lasing mode.

In the real system, once the pump reaches the smallest of these thresholds the solution with $D_0 = D_0^\mu$ turns on. This mode then begins to contribute to the hole-burning term in (9). For all higher pump values this term induces nonlinear interactions by reducing the inversion, raising the thresholds for the higher modes and, in general, changing both their frequencies and spatial distributions. Thus, above the first lasing threshold we face a set of coupled, nonlinear differential equations (9), for the unknown interacting lasing modes $\Psi_\mu(\vec{r})$ and frequencies $k_\mu$. From a practical standpoint, the most efficient way to solve this problem is to characterize these modes with a tractably small set of variables, by expanding
FIG. 1. (Color online) Trajectories of scattering matrix poles with increasing pump strength \(D_0\). (Inset) Schematic of the 1D slab resonator used. Its length \(L = 1\) and index \(n = 1.5\). Gray dots indicate that the pump covers the whole resonator. Solid curves show the pole trajectories when the gain-induced dielectric constant \(\epsilon_g\) is given by Eq. (12), with gain parameters \(k_g = 15/L\) and \(y_\perp = 3/L\). Different symbols lying along each trajectory represent different pump strengths: \(D_0 = 0\) (filled squares), 0.1 (open squares), 0.2 (filled circles), 0.3 (open circles), and 0.4 (filled triangles). At \(D_0 = 0\), the poles are the resonances of the passive cavity, which all have the same imaginary part in this case. Stars indicate the real frequencies \(k^{(\mu)}\) of the corresponding TLMs, which arise for different pump values, \(D_0 = D_0^0\) in general. In Eq. (17), we associate a basis set of TCF states with each TLM; each TCF corresponds to adding a different gain dielectric function to the medium, which pulls a different pole through the same \(k^{(\mu)}\). The dashed lines show this process for these four poles; here we define an increasing dielectric constant \(\epsilon_g\) by \(\epsilon_g = \epsilon_0 + \eta_m\) (0 ≤ \(s\) ≤ 1), where \(\eta_m\) is the TCF eigenvalue introduced in Eq. (17) at the frequency of the first lasing mode. The dashed and solid lines for the first mode (red) coincide.

them in an appropriate choice of basis functions. The original formulation of the SALT employed the following basis set:

\[
\begin{align*}
[\nabla^2 + \epsilon_0(\vec{r})K_0^2(\vec{r})] & \varphi_n(\vec{r}, k) = 0, \quad \vec{r} \in C \\
[\nabla^2 + n_0^2k^2] & \varphi_n(\vec{r}, k) = 0, \quad \vec{r} \notin C,
\end{align*}
\]

(14)

where \(K_\mu\) are complex and \(k\) dependent. The basis states \(\varphi_n(\vec{r}, k)\) were called the “constant flux” (CF) states, and they satisfy an out-going boundary condition at the cavity boundary \(\partial C[29]\). Within \(C\), they obey a wave equation with the complex frequency \(K_\mu\), analogous to (13). Outside, they obey a wave equation with real frequency \(k\) and are required to be outgoing at infinity. The total electromagnetic energy flux outside \(C\) is conserved, as it must be for a physical mode.

The “constant-flux” condition outside \(C\) can be satisfied by a variety of complete non-Hermitian basis sets. The specific CF basis (14), used in Refs. [16,24–26], was chosen because of its similarity to the equation defining the resonances; it differs from (13) only by having real \(k\) outside the cavity. If the cavity dielectric \(\epsilon_0\) is constant and the pump is uniform (\(F = 1\)), then each TLM is a CF state; and (ii) the complex frequency \(K_\mu(k)\) of the CF state is very close to the complex frequency of a passive cavity resonance [16,24]. To be precise, the CF frequency corresponding to a TLM is

\[
K_{\mu}^{(t)} = \left[1 + \frac{\gamma_\perp D_0/\epsilon_c}{k_\mu^{(t)} - \kappa_a + i\gamma_\perp}\right]^{1/2} k_\mu^{(t)}.
\]

(15)

If we define \(K_\mu = q_n - i\kappa_\mu\) (suppressing \(k\) dependence) and assume that the lasing frequency is close to the atomic frequency, it is easily shown [24] that

\[
K_\mu^{(t)} = \kappa_\mu + \frac{\gamma_\perp q_\mu}{\gamma_\perp + \kappa_\mu},
\]

(16)

which is the familiar line-pulling formula for the single-mode lasing frequency [1], with \(q_\mu, \kappa_\mu\) playing the role of the cavity frequency and linewidth. This emphasizes the relationship of the SALT to earlier theories that identified lasing modes with passive cavity resonances.

When the cavity dielectric function \(\epsilon_c\) and/or the pumping profile \(F\) is nonuniform, the TLMs are not given by a single CF state, and each must be written as a superposition of CF states. In Ref. [25], it was found that practical SALT calculations can be performed using a basis of 20–50 CF states. However, when the pumping is nonuniform, the rate of convergence of the CF basis set is poorer. Although the CF state definition (14) takes \(\epsilon_0(\vec{r})\) into account, it does not include the pump profile \(F(\vec{r})\) as an independent parameter; effectively, these CF states correspond to a pump profile proportional to \(\epsilon_0(\vec{r})\).

The above drawbacks motivate us to introduce a new basis set for the SALT equations. These basis functions are still CF states in the sense that they obey the real-\(k\) out-going boundary conditions. However, their definition accounts for nonuniformity in both the cavity dielectric function and the pump profile, allowing us to assign a basis set to each TLM, with one of the basis functions exactly equal to the TLM. We will see that the nonlinear above-threshold solutions can be expanded with a minimum number of these basis functions, resulting in a marked improvement in the performance of the SALT.

To avoid confusion, we henceforth refer to the original CF states (14) as uniform constant flux (UCF) states, and the new basis states as threshold constant flux (TCF) states.

### III. THRESHOLD CONSTANT FLUX STATES AND SALT EQUATIONS IN CF BASES

#### A. Threshold constant flux states

We define the TCF states by:

\[
[\nabla^2 + \epsilon_0(\vec{r}) + \eta_n(k) F(\vec{r})]u_n(\vec{r}, k) = 0, \quad \vec{r} \in C \\
[\nabla^2 + n_0^2k^2]u_n(\vec{r}, k) = 0, \quad \vec{r} \notin C,
\]

(17)

where \(\eta_n\) are complex and \(k\) dependent, and \(u_n(\vec{r}, k)\) are outgoing with frequency \(k\) at infinity. \(F(\vec{r})\) is the spatial pump profile defined in (8). For each \(k\), there exists a discrete set \(\{u_n(\vec{r}, k), \eta_n(k)\} | n = 1, 2, \ldots\} of solutions to (17). We refer to \(\eta_n\) as the TCF eigenvalue, for reasons that will become clear.

Like the UCF frequencies \(K_\mu\), the TCF eigenvalues \(\eta_n(k)\) are complex, and not real, due to the open (non-Hermitian) boundary condition. One can show that \(\text{Im} [\eta_n(k)] < 0\), which implies amplifying behavior similar to the condition \(\text{Im} [K_\mu] < 0\) for the UCF states. In (17), \(\eta_n(k) F(\vec{r})\) plays the role of a
complex amplifying dielectric function with the same spatial profile as the pump, so \( \eta_n(k) \) physically is the scale of the amplifying dielectric constant necessary for that TCF to reach threshold and emit at wave vector \( k \). As previously stated, if we choose \( k = k_{\mu}^{(1)} \), then one of the basis functions matches the solution \( \psi^{(1)}_\mu \) for the threshold lasing equation (12):

\[
\eta_n[k_{\mu}^{(1)}] = \psi^{(1)}_\mu(\vec{r}) \tag{18}
\]

for index \( n \) such that

\[
\eta_n[k_{\mu}^{(1)}] = \frac{\gamma_\perp D_0^\mu}{k_{\mu}^{(1)} - k_\alpha + i\gamma_\perp}. \tag{19}
\]

Note that TLMs and TCF states both satisfy linear equations and hence have no overall scale, so the same normalization must be assumed in (18). Thus each infinite TCF basis set is associated with one true TLM, indexed by \( \mu \). Slightly above threshold, this one TCF state serves as a very good approximation for the first lasing mode. Well above threshold, the lasing mode must be constructed from a superposition that includes the other TCF states (the lasing frequency \( k_\perp \) will also change slightly from its threshold value as the pump increases, and the TCF states will adjust accordingly). As noted, these other TCF states correspond to different values of \( \epsilon_c \) that would also lead to lasing at \( k_\alpha \), values that are not realized by the two-level gain medium of the MB equations. In the S-matrix picture, they correspond to moving a different pole through the real axis at \( k_{\mu}^{(1)} \), as indicated in Fig. 1. Higher lasing modes can likewise be expanded using TCF states with different \( k_\mu \).

The TCF states are not power-orthogonal but obey a self-orthogonality relation:

\[
\int_C d^d\vec{r} F(\vec{r}) u_n(\vec{r}, k) u_m(\vec{r}, k) = \delta_{nm}. \tag{20}
\]

We use the superscript \( d \) to indicate the dimensions of the system here and in the following discussion. We assume degenerate \( \eta_n \)'s are handled, as usual, by choosing the basis so that (20) is satisfied. It follows that any sufficiently regular function having the same out-going boundary condition (with frequency \( k \)) can be expanded in the TCF basis \( \{u_n(\vec{r}, k)\} \). For the uniform case, the UCF and TCF states are the same, with eigenvalues related by

\[
\eta_n(k) = \epsilon_c \left(K_\alpha^2/k^2 - 1\right). \tag{21}
\]

Interestingly, basis states of the UCF type were first defined and used by Kapur and Peierls [30] in the context of nuclear decay, long before their introduction to optical physics by Türeci et al. [16]. The \( k \) dependence of the Kapur-Peierls basis set was considered inconvenient, and it was largely superseded by the use of S-matrix approximations, which do not form a complete basis set but are useful when single-pole approximations are valid (and the amplifying behavior at infinity is ignored) [31]. In our present situation, the appearance of internal amplifying eigenvalues is much more natural, for there is truly a gain medium within the cavity! The Kapur-Peierls (CF) approach, and not the resonance approach, is thus the natural one for describing the laser; and with the availability of modern computers, the fact that the basis is \( k \) dependent does not pose any serious difficulty.

**B. Threshold lasing conditions**

We have seen that the first TLM, having frequency \( k = k_{\mu}^{(1)} \), corresponds exactly to a single TCF state \( u_{\mu} [\vec{r}, k_{\mu}^{(1)}] \) and that the other TCF states must be included above threshold, even though they are not possible TLMs for the actual system. We can find the first TLM by computing the TCF states and \( \{\eta_n(k)\} \) over a range of frequencies close to the gain center \( k_\alpha \). For a fixed choice of \( \{\eta_n(k)\} \), Eq. (19) will yield a complex (unphysical) value for \( D_0 \), but when \( D_0 \) passes through the real axis at \( k = k_{\mu}^{(1)} \), the value of \( \eta_{\mu=0} \) defines a TLM according to (18) (19) (see Fig. 2). The first lasing mode is then the TLM with the smallest \( D_0^\mu \). The other TCFs for that TLM are \( \{u_m [\vec{r}, k_{\mu}^{(1)}] | m \neq n\} \).

To identify which \( \eta_n \) will generate low threshold TLMs, for real \( D_0 \), we can rewrite (19) explicitly as

\[
k = k_\alpha - \frac{\Re[\eta_n(k)]}{\Im[\eta_n(k)]} \gamma_\perp. \tag{22}
\]

\[
D_0 = -\Im[\eta_n(k)] \gamma_\perp \left[1 + \left(\frac{k - k_\alpha}{\gamma_\perp}\right)^2\right]. \tag{23}
\]

with \( k = k_{\mu}^{(1)} \). From the expression in brackets in (23), \( |k - k_\alpha| \) should be as small as possible—and hence, via (22), so should \( |\Re(\eta_n)| \). From the prefactor in (23), \( \Im(\eta_n) \) should also be small, and this condition becomes relatively more important than the first when \( \gamma_\perp \) is large, i.e., the gain curve is broad. Thus, the relevant TCF states are those lying within a “window” around \( \Re(\eta) \approx 0 \), \( \gamma_\perp \); within this window, states with \( \Im(\eta) \) closest to zero (i.e., requiring the least gain) are favored. This analysis agrees with the numerical results shown in Fig. 2.
We can also express the threshold lasing mode in terms of the UCF modes \((14)\). As noted in Sec. II C, for nonuniform \(\epsilon_c\) and/or \(F\) it is necessary to use a superposition of UCF modes:

\[
\Psi_m(\vec{r}) = \sum_n \alpha_n^m \varphi_n(\vec{r}),
\]

\[
\alpha_n^m = \frac{\gamma_m D_\mu^{(0)}}{K_\mu - k^2} \sum_n \int_C d^2 \vec{r} F(\vec{r}) \varphi_n(\vec{r}) \varphi_n^*(\vec{r}) \alpha_n^m,
\]

with \(k = k^{(0)}\). This formulation of the SALT was used in Ref. \([25]\) to analyze 2D random lasers.

To illustrate the advantage of the TCF basis for nonuniform cavity dielectric function \(\epsilon_c\) and pumping profile \(F\), we study a 1D resonator of length \(L = 1\). The refractive index is \(n = 1.5\) for \(0 < x < 0.25\) and \(n = 3\) for \(0.25 < x < 1\). Only the left half of the cavity is pump, i.e., \(F(x) = 1\) \((0 < x < 0.5), 0\) \((0.5 < x < 1)\). The TCF state corresponding to the first TLM, with threshold \(D_0\) = 0.611, is plotted in Fig. 3(a), along with the UCF state, making the largest contribution to this TLM. The TCF state is tailored to the pump profile and is only amplified in the pumped region, whereas, as already noted, the UCF states have no knowledge of the pump profile and exhibit amplification within the entire cavity, including the unpumped region. The TCF state shown in the figure represents only 54.0% of the total weight in this superposition \([32]\).

In order to reproduce the actual TLM, we must superpose many UCF states to cancel the amplification in the unpumped region. In Fig. 3(b) we plot the lasing frequencies \(k^{(0)}\) and (noninteracting) thresholds \(D^{(0)}_\mu\) of the six TLMs with the lowest thresholds obtained by solving \((19)\) and \((24)\) with 20 UCF states, respectively. The largest deviation between the TCF and UCF thresholds is 0.68%, and the frequency differences are below 0.1%.

In more complex lasers, e.g., the 2D random lasers of Ref. \([25]\), a still larger UCF basis set is required to achieve results comparable with the TCF basis. In Fig. 4, the cavity \(C\) is defined by a disk of radius \(R = 1\), in which we randomly place 600 dielectric particles of radius \(\sim R/80\) and index \(n = 1.2\). In

![FIG. 3. (Color online) (a) Spatial profile of the first threshold lasing mode of a 1D slab resonator of length \(L = 1\) (solid blue curve). This TLM corresponds exactly to a TCF state. The matching UCF state, having the largest overlap with this lasing mode, is shown for comparison (red dashed curve). (Inset) Schematic of the resonator. The refractive index is \(n = 1.5\) for \(0 < x < 0.25\), and \(n = 3\) for \(0.25 < x < 1\). Only the left half of the cavity is pump, i.e., \(F(x) = 1\) \((0 < x < 0.5), 0\) \((0.5 < x < 1)\). The TCF state corresponding to the first TLM, with threshold \(D_0 = 0.611\), is plotted in Fig. 3(a), along with the UCF state, making the largest contribution to this TLM. The TCF state is tailored to the pump profile and is only amplified in the pumped region, whereas, as already noted, the UCF states have no knowledge of the pump profile and exhibit amplification within the entire cavity, including the unpumped region. The TCF state shown in the figure represents only 54.0% of the total weight in this superposition \([32]\).

In order to reproduce the actual TLM, we must superpose many UCF states to cancel the amplification in the unpumped region. In Fig. 3(b) we plot the lasing frequencies \(k^{(0)}\) and (noninteracting) thresholds \(D^{(0)}_\mu\) of the six TLMs with the lowest thresholds obtained by solving \((19)\) and \((24)\) with 20 UCF states, respectively. The largest deviation between the TCF and UCF thresholds is 0.68%, and the frequency differences are below 0.1%.

In more complex lasers, e.g., the 2D random lasers of Ref. \([25]\), a still larger UCF basis set is required to achieve results comparable with the TCF basis. In Fig. 4, the cavity \(C\) is defined by a disk of radius \(R = 1\), in which we randomly place 600 dielectric particles of radius \(\sim R/80\) and index \(n = 1.2\). In
Fig. 4(a), we subject the entire cavity to a white noise pump,\[ F(\vec{r}) = 1 + \xi(\vec{r}),\] with \( \max|\xi(\vec{r})| = 0.3 \). We find that 50 UCF states must be included in the UCF expansion in order to achieve good agreement between the threshold solutions of (24) and the TCF predictions (22) and (23). When we pump only part of \( C \) (keeping the scatterer configuration fixed), more UCF states are needed to correctly reproduce the TLMs, even in the absence of the pump noise. In Fig. 4(b), the pump covers a central area of radius \( R/2 \). We find that a superposition of 200 UCF states is required to generate a TLM whose false-color intensity plot (inset) is indistinguishable by eye from the corresponding TCF state (not shown). Even with this many UCF states, the computed TLM intensity profile still differs significantly from the exact (TCF) profile when plotted along any arbitrary direction, as shown in the main figure. The reason so many UCF states are required is that the TLM (and the corresponding TCF state) is amplified only up to the boundary of the pump region, whereas each UCF state, like the uniform pumped system, is amplified up to the boundary of \( C \) [25]. Using these 200 UCF states, the calculated mode threshold and frequency are \( D_0 = 0.142 \) and \( k = 30.011 \); the exact TCF results, from (22) and (23), are \( D_0 = 0.140 \) and \( k = 30.006 \).

C. Above-threshold lasing modes

Above threshold, each lasing mode can be efficiently expanded as a superposition of TCF states:

\[ \Psi_{\mu}(\vec{r}) = \sum_n a_n^{\mu} u_n(\vec{r}, k_\mu). \]  

This expansion automatically satisfies the appropriate outgoing free wave equation outside \( C \). By inserting the above expansion into (9), we write the latter as

\[ \frac{D_0 \Psi_{\mu}(\vec{r})}{1 + h(\vec{r})} = \sum_n \eta_n \gamma_\mu a_n^{\mu} u_n(\vec{r}). \]  

Following the procedures used in Ref. [28], we multiply both sides of (27) by \( F(\vec{r}) u_n(\vec{r}) \), integrate \( \vec{r} \) over \( C \), and invoke the self-orthogonality property (20) to find the SALT equation in the TCF basis:

\[ D_0 \sum_{n'} T_{nn'} a_{n'}^{\mu} = a_\mu^{\mu}, \]  

Equation (28) is a set of nonlinear fixed-point equations above threshold, one for each lasing mode. In general, the complex matrix \( T_{nn'}(k) \) which we refer to as the lasing map, has complex eigenvalues. Because the pump strength \( D_0 \) is a real variable, the unknown lasing frequency \( k_\mu \) must be such that one of its (nonlinear) eigenvalues is real and equal to \( 1/D_0 \). This is achieved by tuning \( k_\mu \) to find the values at which the different eigenvalues correspond to the different modes cross the real axis, as follows. (This procedure is the same as for the UCF basis, and was described in Ref. [26].) The first threshold and lasing frequency are found simply by solving (22) and (23) self-consistently, as described in the previous section; these equations are the diagonal form of (28) at threshold. The associated TLM is proportional to this solution, with vanishing overall amplitude. We then increase \( D_0 \) in small increments and use the solution for the smaller pump value as a starting point for the nonlinear solver. At each step, the nonlinear solver adjusts the frequency \( k_\mu \) so the corresponding eigenvalue of \( T_{nn'}(k_\mu) \) is real. From the modified lasing map, which includes the hole-burning term, we can determine if a second mode has reached its (interacting) threshold [26]. A similar procedure works for third and higher modes and has been shown to work for systems as complex as a 2D random laser with eight modes turned on [25].

In earlier works, the lasing map was written in the UCF basis. This has the same form as (28), with a slightly different matrix operator:

\[ T_{nn'} \equiv \frac{\gamma_\mu \gamma_{n'} k_\mu^2}{K_n^2 - k_\mu^2} \int_C d^2 r \frac{F(\vec{r}) \psi_\mu(\vec{r}) \psi_{n'}(\vec{r})}{1 + h(\vec{r})}. \]  

At threshold (\( h \rightarrow 0 \)), we recover the threshold lasing equation (24). The solution algorithm is identical to that for the TCF map, except that the full matrix solution must be performed even at the first threshold since the UCF map is not diagonal.

Figure 5 compares the lasing modes obtained from (28) and (29) for the 1D slab resonator that we studied earlier in Fig. 3. For \( D_0 = 1.264 \), there are two lasing modes. (This value of \( D_0 \) is approximately twice the first lasing threshold, \( D_0^{\mu=1} = 0.611 \).) Using 20 basis functions for both methods, we find good agreement in the predicted spatial profiles. Figure 5(b) shows the largest expansion coefficients of the two modes in the TCF and UCF bases. We find that both modes retain a dominant component in the TCF basis, even when the system is significantly above threshold. As the pump strength increases, the spatial hole burning term changes \( \epsilon_\mu(\vec{r}) \), so the weights of the dominant components in the TCF basis gradually decrease, but they remain larger than 80% in the calculated range. In contrast, the largest components of the two modes in the UCF basis are less than 60%.

We remark that we could in principle absorb the hole-burning denominator \( 1/[1 + h(\vec{r})] \), calculated at the pump strength \( D_0 - \delta D_0 \), into the profile function \( F(\vec{r}) \) to produce an even better set of modified TCF states for the nonlinear calculation at \( D_0 \). This is essentially an alternative means of solving the nonlinear problem by keeping the self-consistent equation almost diagonal in an evolving basis; however, it is usually too computationally expensive to recompute the TCF states this way.

IV. APPROXIMATE ANALYTIC SOLUTION OF THE SALT EQUATIONS

A. Alternative fixed-point equation

Analyses of the MB equations, either in the single-mode or multimode lasing regime, almost always employ the near threshold approximation, in which the infinite-order nonlinearity of Eqs. (5), (6), and (28) is truncated at cubic order to give a near-threshold approximation to the solution. (An exception to this is the work of Mandel and coworkers [22,23] discussed in Appendix B.) Based on this cubic approximation, and the
approximation of a closed cavity, Haken and Sauermann (HS) long ago derived a set of constrained linear equations for the modal intensities in the multimode regime [21]. The HS equations have been studied further [1,33] and have been used to analyze random and complex lasers in recent years [34,35]. However, the results are unsatisfactory, as shown by Türeci et al. [16]. The cubic nonlinearity in the HS equations leads to a saturation of modal intensities, in disagreement with the linear increase expected on general grounds and found by more exact treatments [17,24]. It also allows many more modes to turn on above threshold in a 1D slab resonator. The properties of the resonator are given in the caption of Fig. 3. The pump strength $D_0 = 1.264$ is slightly higher than twice the first threshold. The solid lines and circles are the results of (28) and (29), respectively, both using 20 basis functions. (b) Weights of the largest expansion coefficients of both modes in the TCF (solid curves) and UCF (dashed curves) bases. The second mode has an interacting threshold $D_0 = 0.89$.

In order to develop the desired approximation, we first reexpress the lasing equations in terms of the inverse of the map $T_{nn}(k)$ defined in (28). This inverse map has the same fixed points but is much more convenient to work with. We multiply both sides of (27) by $[1 + h(\vec{r})]$ and repeat the steps leading to (28), i.e., projecting the two sides onto the TCF basis and using the self-orthogonality property (20). The result is

$$
\sum_{n'} \tau_{nn'} \eta_{n'\mu} = D_0 \eta_{n\mu},
$$

where $h_{nn}(k) = \int_{C} d\vec{r} F(\vec{r}) h(\vec{r}) u_n(\vec{r}, k) u_n(\vec{r}, k)$. Note that (30) has the same form as (28), but with the quantity $D_0$, which plays the role of the eigenvalue, inverted. This implies that $\tau = T^{-1}$, which can be confirmed by multiplying the two operators and using the completeness and self-orthogonality of the TCF states.

The operator $\tau$, through the term $h_{nn}(k)$, contains only a second-order dependence on the lasing modes, in contrast to the infinite-order dependence occurring in $T$. Thus, (30) possesses only a cubic nonlinearity, but this is not the same cubic nonlinearity that appears in the HS theory. No Taylor expansion has been performed; the inverse lasing map is exact at all pump values, and we are still working with infinite-order nonlinearity in the conventional sense of using a dielectric function which contains the field to infinite order.

We could, in principle, use the inverse map $\tau$ to solve the SALT equations, in the same way that we used $T$. Preliminary investigations show that such an approach is possible, and may have some interest, but we will not pursue this further here. Our aim is instead to introduce the "single-pole approximation" (SPA) into (30). This gives a simple approximate solution that is very easy to implement and yields important analytic results.

### B. Single-pole SALT equations

The single-pole approximation was introduced in Ref. [16] to show the connection between the SALT equations, which solve the MB equations with minimal approximations (principally the RWA and the stationary inversion approximation) [17], and the HS equations which employ many more approximations. Aside from the aforementioned cubic approximation, the HS theory assumes that the lasing mode is accurately described by a passive cavity mode. As we have seen, even the threshold lasing mode is not a passive cavity mode: It is neither a closed cavity mode (as assumed by HS), nor a passive cavity resonance, as is often assumed in the literature. Furthermore, above threshold the nonlinearity mixes in other TCF states, which changes the spatial distribution, amplitude, and frequency of the lasing mode. This effect is quite important in low-$Q$ cavities, such as the random lasers treated in Ref. [25], and the full SALT theory describes this effect very well.
high-Q cavities, the mixing in of other TCFs is much weaker, because the scattering from the gain medium is so much weaker than the scattering from the cavity itself. Therefore, it is reasonable to assume that the lasing modes above threshold have the same spatial profile as the TLM, with an amplitude that can increase with $D_0$. This is equivalent to taking only one term in the expansion of the cavity Green’s function in the CF basis; since each term has a single pole in the complex plane, Türeci et al. [16] called this approach the single-pole approximation (SPA).

To be precise, the SPA assumes that

$$\Psi_{\mu}(r) = \sum a_{\mu n}^0 u_n(r, k_{\mu}) \approx a_{\mu n}^0 u_n(r, k_{\mu}^{(0)}) \equiv a_{\mu n}(r), \quad (32)$$

where $u_n(r)$ is the TCF which is equal to the TLM at threshold and $k_{\mu}^{(0)}$ is the threshold value of the lasing frequency. With this approximation the additional index $n$ is redundant and can be omitted, as we do henceforth. Thus the SPA assumes both that the lasing modes are fixed as TLMs and that the lasing frequencies are fixed to be their threshold values. The remaining quantities to be calculated are just the number of modes and their amplitudes $a_{\mu n}(D_0)$ at a given pump value [36]. This also necessitates finding the interacting thresholds $D_{0,\text{int}}^\mu$.

With this approximation the nonlinear matrix equation (30), after canceling a common factor $a_{\mu n}$, is linear for the modal intensity $I_{\mu} \equiv |a_{\mu n}|^2$:

$$D_0^\mu - 1 = \sum_{\nu} \Gamma_{\mu \nu} A_{\mu \nu} \equiv \Gamma_{\mu} \chi_{\mu \nu}, \quad (33)$$

$$\chi_{\mu \nu} \equiv \int d^3 r F(\vec{r}) \left[ a_{\mu n}^0(\vec{r}) \right]^2 |u_{\nu}(\vec{r})|^2. \quad (34)$$

Here $D_0^{\mu} = \eta_{\mu}/\gamma_{\mu}$ are the noninteracting thresholds for the TLMs, which are obtained together with $k_{\mu}^{(0)}$ at threshold using (22) and (23). Because the frequencies of the modes are assumed to be fixed, the spectral gain factor $\Gamma_{\mu}$ and the “interaction constants” $\chi_{\mu \nu}$ are pump-independent quantities. Note also that every quantity in Eq. (33) is real except for $\chi_{\mu \nu}$, which must have some imaginary part if the cavity is open. This inconsistency is a consequence of the single-pole approximation; however, the higher $Q$ the cavity, the smaller is the imaginary part, and for most cavities of interest it is acceptable to neglect this imaginary part. Henceforth we will use the approximation $\chi_{\mu \nu} \approx \text{Re}[\chi_{\mu \nu}]$ and simply denote the real part with the same symbol. With this approximation, the matrix $\chi_{\mu \nu}$ is real and has positive elements.

The above result, which we will term the SPA-SALT, bears a remarkable resemblance to the HS equations. Those equations take the form

$$1 - \frac{\kappa_{\mu}}{D_0} = \sum_{\nu} \Gamma_{\mu \nu} A_{\mu \nu} \quad \text{for all } \mu = 1, \ldots, N. \quad (35)$$

It can be shown that the cavity decay rate $\kappa_{\mu}$, a quantity inserted by hand in that theory, is simply $D_0^\mu$ in the SALT, which is calculable once the cavity and pump profile are given. The coupling matrix in the HS equations has exactly the same form as in the SPA-SALT, except that HS used closed cavity modes (not the real part of the open cavity TLMs) and did not take into account the pump profile, $F(\vec{r})$. However, the different dependence of (35) on $D_0$ in comparison to (33) leads to very different behavior at large pump values. For pumps near the first threshold, the two equations are approximately the same, but at large pump it is easy to show that the modal intensities in the HS theory saturate to a constant, whereas in the SPA-SALT they are proportional to $D_0$. (It should be noted that $D_0$ in the MB equations, which we refer to as the pump, is actually the equilibrium value of the inversion in the absence of laser emission. When one has a multilevel laser with a true pump between upper and ground levels which are distinct from the lasing transition, the quantity $D_0$ is a function of the pump which is linear at small pumps, but saturates eventually, and is bounded by the value corresponding to complete steady-state inversion of the lasing levels.)

C. General solution of the SPA-SALT equations

Let us rewrite the SPA-SALT equation (33) as

$$D_0^\mu - 1 = \sum_{\nu} A_{\mu \nu} I_{\nu}, \quad A_{\mu \nu} \equiv \Gamma_{\nu} \chi_{\mu \nu}. \quad (36)$$

This seems to be simply an inhomogeneous linear system to be solved by inversion, but in fact it is more complicated, for we have not indicated the number of modes to be summed over. Let us suppose that we have solved the noninteracting threshold conditions (22) and (23) for a given $\epsilon_{\mu}(\vec{r})$ and $F(\vec{r})$, obtaining a subset of $M$ TLMs $\{\mu_{\nu}(\vec{r}) \mid \nu = 1, \ldots, M\}$, with real noninteracting thresholds $D_{0\nu}$ less than some cut-off value, $D_{0,c}$ (taken to be much higher than the first lasing threshold). For a given $D_0$, the indices $\mu, \nu$ occurring in (36) are those corresponding to lasing modes that have turned on. We have used this fact in deriving (33), where we divided out the common factor $a_{\mu n}$, which is valid only if $a_{\mu n}$ is nonzero. Hence (33) is a constrained inversion problem; for each value of $D_0$, we must construct the matrix $A_{\mu \nu}$, from the correct subset of the $M$ TLMs at our disposal.

We wish to find an ordered set of matrices $A^{(1)}_{\mu \nu}, A^{(2)}_{\mu \nu}, \ldots, A^{(N_{\text{max}})}_{\mu \nu}$, as well as the associated interacting thresholds $D_{0,\text{int}}^{\mu \nu}$, which are the values of $D_0$ at which the $\mu$-th mode turns on. Because the SPA-SALT includes the effects of nonlinear modal interactions, these differ from the noninteracting thresholds $D_{0\nu}$. In fact, $N_{\text{max}}$ often is less than $M$, since some of the candidate modes may never turn on at any pump value, as we will see below. For a given $D_0$, let us suppose that $N$ lasing modes have turned on. Without loss of generality, we assume that the indices for these lasing modes are $\mu = 1, \ldots, N$. We now have a nonsparse $N \times N$ matrix $A_{\mu \nu}$, and can invert (33) to obtain

$$I_{\mu} = c_{\mu} D_0 - b_{\mu}, \quad \mu = 1, \ldots, N. \quad (37)$$

From this, we see that the intensity of each lasing mode increases linearly with $D_0$, between each threshold, no matter how many modes are lasing or how far the laser is above threshold.

To find the next matrix $A^{(N+1)}_{\mu \nu}$ we must find the lowest interacting threshold $D^{N+1}_{0,\text{int}}$ for the remaining set of $M - N$
modes. To do this, we note that (37) is valid for \(D_{0,\text{int}}^{N} \leq D_{0} \leq D_{0,\text{int}}^{N+1}\) (the lasing intensities are continuous at each threshold although their slopes are not). At the upper limit of this range, \(D_{0} = D_{0,\text{int}}^{N+1}\), we can equally well add mode \((N+1)\) to this matrix equation. The resulting equation would yield identical solutions for \(I_{1}, \ldots, I_{N}\), plus the solution \(I_{N+1} = 0\). Thus we can evaluate (36) for all choices \(\mu = N + 1, \ldots, M\):

\[
D_{0,\text{int}}^{\mu} = D_{0} \left[ 1 + \sum_{\nu=1}^{N} A_{\mu\nu} (c_{\nu} D_{0,\text{int}}^{\mu} - b_{\nu}) \right],
\]

which gives \(N - M\) explicit linear relations for the possible \(N + 1\)st threshold. Evaluating these relations, one simply chooses the lowest value, which is then the correct \(N + 1\)st interacting threshold. This defines a recursive procedure to find all the interacting thresholds and uniquely determine the ordered set of \(A\) matrices required to compute \(I_{\mu}(D_{0})\) for the entire desired range of \(D_{0}\).

Note that we always assume the “nontrivial zero” solution at each (interacting) threshold, i.e., that the physical solution switches from the trivial zero for \(I_{N+1}\) to the nonzero lasing solution, giving rise to a bifurcation with discontinuous slope. When this happens, all the modes which are already turned on experience a negative kink in their slopes at higher thresholds. This behavior is characteristic of lasers when higher modes turn on, and the SPA-SALT captures it in a simple manner.

Once the constraints on Eq. (36) are implemented in this manner, the solution of the SPA-SALT equations requires just \(N_{\text{max}}\) inversions of relatively small matrices generated from the input parameters, \(\{\chi_{\mu\nu}\}, \{\Gamma_{\nu}\}, \{D_{0}\}\). Thus the computational time for solving the SPA-SALT equations is negligible once the TLMs have been calculated. When the single-pole approximation is good, the nonlinear multimode problem becomes only minimally harder than the linear TLM problem, which can be adapted for efficient solution using finite element or boundary element methods [37,38]. In Sec. IV F we compare the SPA-SALT lasing solutions to the exact SALT calculations, finding good agreement. Note that it has already been shown [17] that the exact SALT solutions agree to within a few percentage points with exact time-dependent MB simulations for simple 1D edge-emitting lasers, as long as the conditions for the stationary inversion approximation are well satisfied.

D. Gain-clamping transition

Equation (37) gives a linear relation determining each of the \(N_{\text{max}}\) interacting thresholds of the form

\[
D_{0,\text{int}}^{\mu} = f_{\mu}(\{\chi_{\mu\nu}\}, \{\Gamma_{\nu}\}, \{D_{0}\}) D_{0}^{\mu} \equiv \frac{1}{1 - \lambda_{\mu}} D_{0,\text{int}}^{\mu},
\]

where the function \(f_{\mu} \equiv (1 - \lambda_{\mu})^{-1}\), is the threshold enhancement factor which increases the \(\mu\)th threshold from its noninteracting value, due to the spatial hole-burning of lower threshold modes, which depletes the gain. In simplified treatments of the laser rate equations, in which the cavity mode is assumed perfectly uniform in space, these interactions actually clamp the effective gain so that it no longer increases with the external pump, predicting that no additional modes turn on [1]. In reality, the incomplete spatial overlap of modes prevents perfect gain-clamping and typically additional lasing modes can and do occur. The SPA-SALT gives a much more rigorous criterion for gain clamping at the level of the \(N\)th lasing mode. If \(\lambda_{N} \to 1\), then all higher thresholds are pushed off to infinity and no more modes can turn on for any value of the pump.

Note the analogy here to mean-field phase transitions, for example, where a strong-enough magnetic interaction causes the susceptibility to diverge. Here strong interactions, meaning large values of the coefficients \(\chi_{\mu\nu}(\mu \neq \nu)\), suppress “ordering” of higher modes. Conversely, spatially disjoint or weakly overlapping modes will not be suppressed and their interacting threshold will be approximately equal to their noninteracting thresholds. In addition, higher modes with substantially lower modal gain and \(Q\) values with respect to the first mode(s) will be more easily suppressed. Calculations for various examples indicate that this gain-clamping “phase” of the laser can be reached for realistic lasers. We calculate and discuss the coefficient \(\lambda_{2}\) below.

E. One- and two-mode solutions

To get a feeling for the SPA-SALT solutions, we now present explicit results for one- and two-mode lasing, which illustrate most of the qualitative features of the theory. The single-mode result is trivial. The lowest noninteracting threshold, \(D_{0}^{(1)}\), is found as part of the calculation of the initial set of \(N\) TLMs and of course is the correct first threshold. Eq. (36) is just a scalar equation for the first mode intensity, yielding

\[
I_{1} = \frac{1}{\Gamma_{1} \chi_{11}} D_{0}^{(1)} \left[ D_{0} - D_{0}^{(1)} \right],
\]

where \(\chi_{11}^{-1} \equiv V_{1}\) plays the role of the mode volume, enhancing the power slope if mode one is more evenly distributed over the gain volume. We should point out that \(I_{1}\) should be thought of as the intensity within the cavity. The emitted power is found by integrating the photon flux associated with the TLM \(u_{\mu}(\vec{r})\) over a surface at infinity [16]; the transmissivity of the cavity is implicitly contained in the calculation of the TLM. In Appendix A we show that this power output can be related to a volume integral of the TLM over the gain region of the cavity and that for single-mode lasing within the SPA-SALT one finds

\[
P_{1} = \frac{k_{1}}{2\pi} \int d^{2}r F(\vec{r}) |u_{1}|^{2} \left[ D_{0} - D_{0}^{(1)} \right].
\]
where the interaction coefficient

\[ \lambda_2 = \left[ \frac{D_0^{(2)}}{D_0^{(1)}} - 1 \right] \frac{\chi_{21}}{\chi_{11} - \chi_{21}} \geq 0. \]  

(43)

Note that, as \( D_0^{(2)} > D_0^{(1)} \), as long as the modal interaction coefficient \( \chi_{21} \) is nonvanishing, the interacting second threshold is higher than the noninteracting threshold. The gain-clamping limit is reached when \( \lambda_2 \rightarrow 1 \Rightarrow \chi_{21} = \chi_{11} D_0^{(1)}/D_0^{(2)} \), and the first mode suppresses any second mode for all values of the pump. One sees that strong overlap \( \chi_{21} \approx \chi_{11} \) leads to gain clamping as we expect. Also if the second mode has significantly lower \( Q \) value or is away from the center of the gain curve, the ratio \( D_0^{(1)}/D_0^{(2)} \) is reduced leading to gain clamping for smaller values of \( \chi_{21} \). One way to achieve this limit is in a microcavity laser with passive cavity modes spaced more widely than the gain bandwidth.

When the pump exceeds the second threshold \( D_0^{(2)} \), the modal intensities \( I_1 \) and \( I_2 \) are obtained from Eq. (36),

\[ I_1 = \frac{\chi_{22}/D_0^{(1)} - \chi_{12}/D_0^{(2)}}{\Gamma_1(\chi_{11} \chi_{22} - \chi_{12} \chi_{21})} [D_0 - D_0^{(1)}], \]  

(44)

\[ I_2 = \frac{\chi_{11}/D_0^{(2)} - \chi_{21}/D_0^{(1)}}{\Gamma_2(\chi_{11} \chi_{22} - \chi_{12} \chi_{21})} [D_0 - D_0^{(2)}], \]  

(45)

where the modified intercept \( D_0^{(1)} \) is given by

\[ D_0^{(1)} = \frac{\chi_{22} - \chi_{12}}{\chi_{22} - \chi_{12}^{(1)}} D_0^{(1)} \]  

(46)

The change in intercept indicates that the first mode intensity has a negative kink at the second mode threshold \( [D_0^{(1)} < D_0^{(1)}_{\text{int}}] \), as can also be seen directly from the slope of \( I_1 \), which is reduced from its value of \( 1/\Gamma_1(\chi_{11} D_0^{(1)}) \) in the interval below the second threshold. This kink is always negative because the turning on of a second mode reduces the slope efficiency of the laser in the first mode but vanishes when the interaction coefficient \( \chi_{12} \rightarrow 0 \) and the two lasing modes act independently.

To test the results derived above, we first revisit the 1D laser studied in Sec. III B. Figure 6 shows the growth of modal intensities with \( D_0 \). In the single-mode regime, the result given by (40) agrees very well with the numerical solution of (28), indicating that the single-pole approximation is almost exact. Consequently, the second threshold \( D_0^{(2)} = 0.892 \) is also accurately predicted by (42), which gives \( D_0^{(2)} = 0.899 \). In the two-mode regime we still find good agreement, but the SPA-SALT slightly overestimates the suppression of the second mode. Nevertheless, the total intensity is in good agreement with the full SALT solution.

To demonstrate the accuracy of the SPA-SALT in cases where the mode density is high, we study a uniformly pumped 2D disk laser of radius \( R = 1 \) and index \( n = 3.3 + 10^{-5}i \). The gain is assumed to center at \( \text{Re}[n k_a R] = 66 \) with width \( \gamma_\perp = k_a/40 \). Now there exist high-\( Q \) whispering gallery modes, and

![FIG. 6. (Color online) Modal intensity versus pump strength in a 1D slab resonator. The description of the resonator is given in the caption of Fig. 3. Open symbols show the numerical solutions of (28) and solid lines are the results of single-pole approximation [Eqs. (40), (44), and (45)]. The color scheme is as follows: blue (Mode 1), red (Mode 2), and black (total intensity in the two-mode regime).](http://example.com/fig6.png)

![FIG. 7. (Color) (a) Modal intensity versus pump strength in a 2D disk laser of uniform index \( n = 3.3 + 10^{-5}i \), uniformly pumped. Squares show the numerical solutions of (28) and solid lines are the results of the single-pole approximation (37). (Inset) Zoomed view near the first two thresholds. (b) Modal gain versus pump strength for the first 10 TLMs, calculated with the full SALT, indicating that the 10th TLM will never turn on due to modal interactions, as predicted by the SPA-SALT. The dashed line indicates the fully suppressed 10th mode. The first two modes are too close together to be distinguished in this plot. Modal gain is defined in terms of eigenvalues of the modified lasing map and a mode reaches threshold when the modal gain reaches unity [26].](http://example.com/fig7.png)
we find that first two thresholds are very closely spaced [see inset; Fig. 7(a)] and are four orders of magnitude smaller than those in the 1D example just treated. The SPA-SALT correctly captures the intensity crossover of the first two modes shortly after the second one turns on, and its prediction for the first three modes remains impressively accurate, even after the onset of the seventh mode. As we have seen in Fig. 5(b), the higher-order mode(s) are less single-pole-like compared to the lower-order modes. Thus we expect the SPA-SALT not to work as well for higher-order modes; this can be seen from the noticeable differences in the fifth (black) and seventh (cyan) thresholds given by the SPA-SALT and the full SALT results in Fig. 7(a). Nevertheless, the slopes of all the higher-order modal intensities are still largely correct.

As noted, Eq. (39) gives a criterion for a complete suppression of modes after a certain number of modes $N$ have turned on. Typically if a mode is completely suppressed this equation gives a negative (unphysical) result. This happens for the 10th TLM in the current example. Indeed, the full SALT calculation, using the modified threshold matrix [26], confirms the prediction that the 10th TLM will never turn on [dashed gray curve in Fig. 7(b)].

The SPA is better satisfied the less open is the laser cavity. The random laser is a system in which there is no conventional cavity, only multiple scattering to slow escape. In the most challenging case of a weakly scattering RL, it has no sharp linear resonances at all, only the presence of the gain medium allows strong preference for certain frequencies [25]. In Ref. [25] the modal intensities for a 2D RL were found within the full SALT theory to be a nonlinear function of the pump, unlike all other cases studied. Thus we do not expect the SALT to apply there. Even when the disorder scattering is increased in the RL in order to increase the $Q$, and the intensities are linear in the pump, we find that the SPA-SALT, while it still gives good qualitative results, does not give good quantitative agreement with the exact SALT solutions, as shown in Fig. 8.

\[ P = \frac{1}{4\pi} \oint ds \mathbf{n} \cdot (\mathbf{\hat{E}} \times \mathbf{\hat{B}}) \] (A1)

APPENDIX A: MODAL OUTPUT POWER

In this appendix we derive the modal output power of a 2D cavity from the (internal) modal intensity. The output power is the total flux of the Poynting vector, taken across a loop $\Gamma$ enclosing the cavity:

\[ P = \frac{1}{4\pi} \int_\Gamma ds \mathbf{n} \cdot (\mathbf{\hat{E}} \times \mathbf{\hat{B}}). \] (A1)
In (4), the (out-of-plane) electric field is written as a sum over the modal fields $\Psi_\mu(\vec{r})$, and a similar expression may be written for the (in-plane) magnetic field. We find the time-averaged total output power $\langle P \rangle = \sum_\mu P_\mu$, with the modal power $P_\mu$ given by

$$P_\mu = \frac{I_\mu}{4\pi k_\mu} \int d\vec{r} \{ \frac{\Gamma_\mu D_0 F(\vec{r})}{1 + h(\vec{r})} - \text{Im}[\epsilon(\vec{r})] \} |\Psi_\mu(\vec{r})|^2.$$  

(A2)

In the last step we have used Gauss’s law. Here $\Psi_\mu$ and $P_\mu$ are measured in their natural units $e_c$ and $c^2$, introduced when deriving Eq. (6). Using Eq. (A3), together with the wave equation (9) and its complex conjugate, gives us Eq. (11), which we reproduce here for convenience:

$$P_\mu = \frac{k_\mu}{2\pi} \int d^2 r \{ \frac{\Gamma_\mu D_0 F(\vec{r})}{1 + h(\vec{r})} - \text{Im}[\epsilon(\vec{r})] \} |\Psi_\mu(\vec{r})|^2.$$  

(A3)

This result states that the total power radiated by each lasing mode equals the power that the gain medium delivers into that mode, minus the power that the mode loses through material dissipation (described by $\text{Im}[\epsilon]$).

It is instructive to consider the modal power in the single-pole approximation. Let us suppose that $\text{Im}[\epsilon] = 0$. Combining the general expression for $P_\mu$ in (A3) with the SPA-SALT expression $\Psi_\mu \approx \sqrt{T_\mu} u_\mu$, we obtain

$$P_\mu = \frac{I_\mu}{4\pi k_\mu} \int d^2 r \{ \frac{\Gamma_\mu D_0 F(\vec{r})}{1 + h(\vec{r})} - \text{Im}[\epsilon(\vec{r})] \} |\Psi_\mu(\vec{r})|^2.$$  

(A5)

$$P_\mu = \frac{k_\mu}{2\pi} \Gamma_\mu D_0 I_\mu \int d^2 r |F(\vec{r})| |u_\mu|^2.$$  

(A6)

Here we have used (19) to express $\text{Im}[\eta_\mu]$ in terms of the SPA laser threshold $D_0^{\perp}$. As noted in the main text, in the single-mode regime ($\mu = 1$), the modal power has a particularly simple form: using (33), we can write $I_\mu$ in terms of the pump $D_0$, to obtain

$$P_1 = \frac{k_1}{2\pi} \int d^2 r |F(\vec{r})| |u_1|^2 \left[ D_0 - D_0^{(1)} \right].$$  

(A7)

**APPENDIX B: COMPARISON TO MANDEL APPROACH**

In Refs. [22,23] Mandel and coworkers treated the infinite-order modal interactions in a Fabry–Perot cavity in the single-mode and two-mode regimes. They used the approximations of stationary inversion, and pump-independent lasing modes and frequencies, similar to the SPA-SALT (the SALT of course includes the pump dependence of the lasing modes and frequencies [25]). Unlike the SPA-SALT, they assumed that the fixed lasing modes were Hermitian closed cavity modes (sine waves of real wave vectors). They did not derive a version of the basic constrained linear equation (33) of the SPA-SALT, but instead they derived a single-pole closed-cavity version of Eq. (28). For the single-mode case, Eq. (5) of Ref. [22] is of exactly the same form as Eqs. (43) and (54) of Ref. [16], the earliest version of the SALT, except for their use of closed-cavity modes. Reference [16] applies the single-pole approximation to the direct map but treats the openness of the cavity exactly using non-Hermitian constant flux states; this approximation is not exactly equivalent to the SPA-SALT, which uses the SPA on the inverse map, but gives very similar results to the SPA-SALT at large pump strength.

It is interesting to compare the two methods for the simple case of a uniformly pumped 1D dielectric slab laser of the type considered in Refs. [16,17,24] [see Fig. 1(inset)]. We will compare Mandel’s approach to the full SALT, the most complete form of our theory. Thus our approach differs from Mandel in two major ways. First, we take into account the openness of the cavity exactly and, second, we allow for the change in the lasing modes and modal frequencies above threshold. To vary the quality factor of the cavity, we choose four sets of parameters $\{n, k_0\} = \{1.5, 40\}, \{3, 20\}, \{5, 20\}$, and $\{10, 20\}$ ($k_0$ is the frequency of the gain center). We have shown in Ref. [17] that for the first two sets of parameters the SALT and numerical solutions of the MB equations agree very well, so we can take the SALT results as correct.

The rescaled model intensity $\langle I'_\mu \equiv \Gamma'_\mu I_\mu \rangle$ in the single-mode regime in Mandel’s approach is given in our notation by

$$I'(D_0) = \frac{1}{4} \left[ \frac{D_0}{D_0^{(1)}} - 1 - \sqrt{\frac{8}{\frac{D_0}{D_0^{(1)}} + 1}} \right].$$  

(B1)

The dependence on the refractive index of the cavity is contained in the first threshold, $D_0^{(1)}$, which is not calculated in the Mandel approach but is assumed known and used to normalize the pump. The gain parameters ($k_0$ and $\gamma_\perp$) only enter in the scale factor ($\Gamma'_\mu$) and implicitly again through $D_0^{(1)}$. Note that the Mandel single-mode result has an additional square-root dependence on the pump, which is not present in the SPA-SALT. This difference arises because, as already noted, the single-pole approximation is made at a different point in the two derivations. The full SALT theory does not predict a universal linear dependence on pump and indeed for very low-$Q$ lasers, such as random lasers, the dependence can be nonmonotonic [25].

In Fig. 9 we compare the result given by Eq. (B1) to the SALT. As one might have expected, the two approaches agree well for the higher-$Q$ cases ($n = 10,5$) but a significant disagreement in the slope of the intensity curves appears for the lower-$Q$ ($n = 1.5,3$) cases. Nonetheless, the Mandel approach for the single-mode case is qualitatively better than HS, which shows an unphysical saturation [16,17].

Next we compare the value of the interacting second threshold $D_0^{(2)}$ given implicitly in Mandel’s method by

$$I'\left[D_0^{(2)}\right] \left[ \frac{D_0^{(1)}}{D_0^{(2)}} + 2 - 2\frac{D_0^{(2)}}{D_0^{(1)}} \right]^2 = \frac{\frac{D_0^{(1)}}{D_0^{(2)}}}{\frac{D_0^{(2)}}{D_0^{(1)}} - 1}.$$  

(B2)

and the result of the SALT in the four cases listed above. We find that Mandel’s approach consistently underestimates the strength of the modal interactions and deviates relatively little from the noninteracting threshold values (see Fig. 10). The highest-$Q$ case agrees most closely with the SALT, but there is some nonmonotonic behavior of the thresholds with $Q$ value in the SALT which we did not analyze in detail. We conclude that the effect of openness accounts for the main...
The difference between the SALT and the Mandel approach, in a Fabry-Perot cavity in which both can be applied. Mandel’s approach is qualitatively better than that of HS but is not as accurate as the SALT and the SPA-SALT, both of which are based on general computational algorithms applicable to arbitrary cavities.

APPENDIX C: PERTURBATIVE CALCULATION OF CORRECTIONS TO THE SPA-SALT

The major approximation in the SPA-SALT is replacing the expansion (26) with a single term, \( \Psi_\mu = a_\mu u_\mu \equiv a_\mu u_\mu \).

FIG. 10. Second interacting threshold in a 1D slab resonator. The cavity and parameters used are the same as in Fig. 9. \( D^{(2)}_0 \) is the second threshold value in the absence of modal interaction. The solid line and crosses are the solution of Eq. (B2), and the dotted line indicates the noninteracting case \( (\gamma = 1/w) \). The results of the SALT are indicated by the different symbols explained in the legend.

FIG. 11. Expansion coefficients of the first lasing mode (left) and the second lasing mode (right) at the second threshold in a 1D slab resonator. The solid curve is the solution of (28) and the dashed line is given by the approximation (C2) and (C3), respectively. The expansion of the first/second mode is dominated by the first/second UCF state with a weight of 90%/84%.

In this Appendix we derive the first-order expression for the nondominant expansion coefficients \( a_\mu^n \) in the single-mode regime. Assuming the dominant component is \( a_1 \), we approximate \( h(\vec{r}) \) by \( \mid a_1 u_1(\vec{r}) \mid^2 = \mid I_1(u_1(\vec{r}) \mid^2 \). Equation (30) for \( a_{n(n>1)} \) is then

\[
D_0 \left. a_n = \frac{a_n}{\kappa_n} + \Gamma_1 I_1 \sum_m \left. \kappa_m^{(1,1)} \right/ \kappa_m a_m, \right. \tag{C1}
\]

By inserting the expression (40) for \( I_1 \), derived in the single-pole approximation, into Eq. (C1), we reduce the latter to a set of inhomogeneous linear equations of \( a_{n(n>1)} \). Equation (C1) can be further simplified by keeping only the \( a_1 \) term in the sum, which leads to

\[
a_n = \frac{\kappa_n^{(1,1)}}{\kappa_m^{(1,1)}} (D_0 - D_0^{(1)}) \cdot \frac{a_1}{\kappa_m}. \tag{C2}
\]

Note that \( \eta_n(k_1^{(1)})/\gamma_1 \) is not \( D_0^{(1)} \), which is \( \eta_n(k_1^{(1)})/\gamma_1 \). In Fig. 11(a) we compare (C2) to the numerical solution of (28) and they agree very well. The system is the inhomogenous 1D resonator considered in the main text, and the pump is tuned to the second threshold (\( D_0 = 0.892 \)).

We can also derive an analytical expression to evaluate the nondominant expansion coefficients of the second mode when it turns on. We assume that its dominant component is \( a_2^{\mu=2} \) and derive

\[
a_2^{\mu=2} = \frac{\kappa_n^{(2,1)}}{\kappa_m^{(1,1)}} \cdot \frac{D_0^{(2)}}{D_0^{(1)}} - 1 = \frac{\eta_n(k_1^{(1)})/\gamma_1}{\gamma_1 D_0^{(2)}}. \tag{C3}
\]

in the same way (C2) is derived. It is easy to check using (36) that the ratio becomes 1 when \( n = 2 \) as it should. The result above is compared with the multipole expansion (28) in Fig. 11(b).
[27] In earlier work we used a less memorable acronym, AISC (ab initio self-consistent laser theory), which we now have dropped. We apologize for any confusion.
[29] The implementation of the out-going boundary condition in various geometries can be found in Refs. [16] and [28].
[32] The weight used here is defined as $|\alpha_{\mu}|/\sum |\alpha_{\nu}|$.
[36] Within the stationary inversion approximation and the SPA the phase of $a_{\mu}^\mu$ is meaningless, as we neglect phase relations between modes and there is only one coefficient in the expansions of $\Psi_{\mu}$. Hence only the modulus $|a_{\mu}^\mu|$ is meaningful, and we will see that the SPA-SALT solves only for $I_\mu = |a_{\mu}^\mu|^2$.
