ABSTRACT
In order to overcome urban space constraints, underground road systems are becoming popular options for cities. Existing literature suggests that accident rates in road tunnels are lower than those in open roads. However, there is a lack of understanding in how the road tunnel environment affects inter-vehicle interactions. In this study, car following data are obtained from traffic video footages of open and tunnel expressways in Singapore. A total of 15,325 car following headways (with car as the follower) are analysed and significant factors affecting headways are found to be speed, and lane. Significant effect of leading vehicle type is only found for tunnel expressway. Headways are generally longer in the tunnel environment. Assessment of collision time measures and safety margins also reveal safer car following behaviour and lower rear-end collision risks in the tunnel expressway. The results are discussed from a behavioural perspective. Overall, the findings show that road tunnels are superior in terms of safety but at reduced traffic capacity.

Keywords: Car following; tunnel expressway; headways; time-to-collision; safety margin; traffic safety

1. Introduction
Urban sustainability is one of the many challenges faced by megacities today. As megacities continue to grow, more space is required for new supporting infrastructure. However, urban expansion is often constrained by limited land space in the city. In order to overcome this limitation, cities have begun to utilise urban underground space for various uses, such as pedestrian links, utility tunnels, retail facilities, and rail systems.

In particular, underground road systems (URS’s) have become increasingly popular. Several studies (Sahlström, 1990; Sterling, 1997; Ronka et al., 1998; van der Hoeven, 2011) acknowledged the strategic use of URS’s, especially in highly developed areas such as central business districts. The reason is that URS’s help to reduce traffic in important city streets and protect the surface environment from noise and emissions. Other advantages of URS’s include shielding motorists from adverse weather conditions and freeing up surface land for other quality uses. With URS’s becoming more extensive, drivers can expect to spend a greater amount of time in road tunnels. However, there is limited knowledge on the impacts of urban road tunnel environment on microscopic driving behaviour, which in turn aggregates into macroscopic traffic performance and safety.
According to environment-behaviour theories, behaviour is the manifestation of the individual’s perspectives and perceptions of the environment. The theory of planned behaviour (Ajzen, 1991; 2005; Steg and Nordlund, 2013) suggests that behaviour is modulated indirectly through intention by personal norms, attitude, subjective norms, and perceived behavioural control. In a free association study by Yeung et al. (2013), it was shown that drivers perceive open and tunnel expressways differently. Several studies had also found drivers to be less receptive towards road tunnels (Serrano and Blennemann, 1992; Amundsen, 1994; Arias et al., 2008; Yeung et al., 2013), with higher scores in negative emotions experienced in tunnels as compared to surface roads. Considering the differences in perceptions and attitudes towards road tunnels, it is reasonable to expect drivers to behave differently in road tunnel environment.

2. Literature review

2.1. Driving behaviour in road tunnels

Several studies have investigated driving behaviour in road tunnels. In a series of driving simulator experiments (Calvi et al., 2012; Calvi and D’Amico, 2013), it was found that the road tunnel environment, as compared to a control open section, resulted in lower driving speeds and differences in average lateral position (further away from tunnel walls). Lower pathologic discomfort was also found in the tunnel interior zones. Interestingly, pathologic discomfort in the tunnel portal areas was found to be higher in a tunnel scenario as compared to the control scenario, and this suggests a causal link with accident rates. In another study, He et al. (2010) studied drivers’ visual attention in various tunnel lengths in on-road trials and found indicative differences in the distribution of gaze time and fixation duration.

Some other studies investigated the effect of various tunnel features. A driving simulator study by Shimojo et al. (1995) revealed that tunnel cross section and signage information indicating the remaining tunnel length had notable effects on driving performance and driving workload. Hirata et al. (2006) examined the effectiveness of accident information on drivers in a simulated tunnel and found that informing drivers about an accident that occurred in the tunnel had a positive effect on safety. Törnros (2000) assessed the effects of several tunnel wall patterns on simulated driving behaviour. Although no significant effect of wall pattern was found, drivers drove at significantly lower speeds in the tunnels compared to surface roads. Kircher and Ahlstrom (2012) investigated the effects of tunnel design and lighting on driver performance in a driving
simulator and found light-coloured walls were more important than strong illumination to keep drivers’ visual attention on the road ahead.

However, most of these studies do not provide a comparative perspective in behaviour between open and tunnel road environments. Thus, they do not give insight into how tunnels will impact traffic behaviour compared to the open roads. Furthermore, these studies were mostly based on single vehicles commuting through light traffic in the road tunnels, either in simulated or real world environments. Hence, there is also a lack of understanding in how the tunnel environment affects inter-vehicle interactions.

2.2. Traffic safety in road tunnels

Road tunnels have lower crash rates compared to surface roads (Amundsen and Ranes, 2000; Lemke, 2000; Ma et al., 2009; Yeung and Wong, 2013). Nonetheless, traffic accidents in road tunnels are of great concern due to their potential for catastrophic outcomes. Nussbaumer (2007) found fatality rates to be more than double in bi-directional tunnels as compared to unidirectional tunnels, presumably due to a higher risk of head-on collisions with vehicles from opposing directions. Fortunately, for practical reasons urban road tunnels mainly carry unidirectional traffic in each tube, thus greatly reducing the possibility of head-on collisions.

As a result, rear-end collision is the most prevalent crash type in urban road tunnels. More than two in three tunnel crashes in Singapore are categorised as rear-end crashes (Meng and Qu, 2012), while single vehicle crashes account for a small fraction of all reported tunnel crashes (Amundsen and Ranes, 2000; Ma et al., 2009; Yeung and Wong, 2013). According to The Handbook of Tunnel Fire Safety (Beard and Carvel, 2012), most tunnel fires are caused by such rear-end collisions.

Road traffic accidents are the most direct measures of traffic safety and accident data have typically been used in traffic safety analyses. However, it is difficult to base traffic safety analyses on accidents because they are rare events (Laureshyn et al., 2010). Furthermore, accident data may have issues such as underreporting and lack of detailed causal information. Hence, evaluation of traffic safety should be more reliant on microscopic behavioural data.

2.3. Traffic safety and car following

A rear-end collision occurs when a following vehicle fails to brake in time to avoid impact with the front vehicle. This is usually a result of inadequate following distance. Typically, the two safety indicators used in
assessing imminent rear-end collisions are headway (or gap) and time-to-collision (TTC) (Oh and Kim, 2010; Bella and Russo, 2011). Vogel (2003) surmised that short headways indicate potential danger while short TTCs represent actual danger. This is consistent with Evans and Wasielewski (1982) who found that accident-involved drivers are more likely to maintain shorter headways than accident-free drivers. Meng and Qu (2012) also demonstrated that rear-end crash rates can be estimated using the likelihood of TTC being below a certain threshold at different traffic volumes.

Many factors may affect drivers’ choice of headway, such as individual differences, situational factors, and other vehicles. Ranney (1999) suggested that as traffic tends towards congestion, the influence of individual and situational factors diminishes while the influence of other vehicles increases. A key factor influencing headway choice is vehicle speed. However, while some studies have found time headways to increase with speed (Colbourn et al., 1978; Puan, 2004; Broughton et al., 2007; Al-Kaisy and Karjala, 2010), other studies found otherwise (Taieb-Maimon and Shinar, 2001; Marsden et al., 2003; Brackstone et al., 2009). Other factors include visibility (Broughton et al., 2007), lead vehicle class (Puan, 2004; Brackstone et al., 2009; Ossen and Hoogendoorn, 2011; Duan et al., 2013), driver culture (Marsden et al., 2003), driver experience (Colbourn et al., 1978), and intervention advisory signage (Michael et al., 2000). Interestingly, most of these studies were conducted on single-lane roads and the effect of the traffic lane travelled in a multilane roadway is yet to be investigated, i.e. whether car following behaviour in the fast lane is different from that in the slow lane.

In order to assess the traffic safety, extended TTC measures such as the time exposed TTC (TET) and time integrated TTC (TIT) have been proposed (Minderhoud and Bovy, 2001). TET takes into account the amount of time that the TTC falls below a predetermined threshold. TIT takes into account both the duration and magnitude of which TTC falls below the threshold. These measures require the analyses of vehicular trajectories over time and are difficult to apply to spot measurements.

Bifulco et al. (2013) proposed the concept of car following waves. Based on psychophysical or Action Point models, car following waves in opening charts provide better regression results in the $DV/DX$ vs $DV$ plane ($DV$ is the relative speed and $DX$ is the distance gap between two successive vehicles) than conventional interpretation of Action Point models in the $DV$ vs $DX$ plane (Brackstone and McDonald, 1999; Brackstone et al., 2002). In essence, the regression coefficient describes the TTC patterns observed in car following.
Zhang et al. (2010) proposed the use of safety margin (SM) as an alternative risk indicator in car
following. The computation of SM considers distance gap, speed, and relative speed, which are main
macroscopic safety indicators (Qu et al., 2014). Lu et al. (2012) discussed that, out of three risk indicators
(time headway, TTC, and SM), SM serves as a suitable quantitative indicator of homeostatic risk perception in
car following because it follows the normal distribution. They also found professional drivers to exhibit lower
SM as compared to general drivers, which implies that professional drivers are willing to drive in a less safe
manner.

3. Objectives of the study

As mentioned, there is a lack of understanding in how the tunnel environment affects inter-vehicle
interactions. This study sets out to examine car following behaviour (with car as the follower) in both open
and tunnel road environments to meet two primary objectives: 1) to identify factors which affect how car
drivers behave in unidirectional car following situations; and 2) to understand from a microscopic behavioural
perspective how traffic safety in road tunnels is different from that in conventional open roads. Headways
(time and distance), TTC, and SM are considered in the analyses. Drawing reference from accident studies, it
is hypothesized that drivers adopt safer microscopic behaviour in the tunnel than in the open road
environment.

4. Methodology

4.1. Data basis

Traffic video footages are obtained for both open and tunnel expressways in Singapore. The main criterion
for site selection is to have similar roadway characteristics in both environments. For open expressway, video
footage is recorded from an overhead pedestrian bridge arching over the Ayer Rajah Expressway (AYE) at the
4.5 km mark. This section of the AYE is relatively straight and consists of six lanes (three in each direction,
separated by a central median). It is also relatively free from lane changing activity as the nearest intersection
is more than one km away. The speed limit of this road section is 90 kph. Data are collected from a 25 frames-
per-second video recorded on 18 September 2012, during the peak hour period from 1700 to 1900 h, for
westbound traffic. The weather was good with no rain for the entire observation period. In order for the video
camera recorder to be as inconspicuous as possible to minimise its influence on motorists’ behaviour, the
“away” view is recorded (see Figure 1a).
For tunnel expressway, the selected site is the 5.4 km mark of Kallang-Paya Lebar Expressway (KPE) tunnel. This section of the KPE is relatively straight and consists of three lanes in each direction – KPE tunnel consists of dual unidirectional tubes. Lane changing activity is minimal since it is located mid-distance between an upstream off-ramp and a downstream on-ramp. The speed limit of this road section is 70 kph. The video footage is requested from the Land Transport Authority KPE Operations Control Centre, which monitors KPE traffic through 24-h traffic cameras. Data are collected from a 25 frames-per-second video recorded on 26 September 2012, during the evening peak hour period from 1700 to 1930 h, for northbound traffic. The external weather was good with no rain for the entire observation period. In the tunnels, the “away” view is also preferred (see Figure 1b) because vehicle headlights in the frontal view tend to create a glare effect in the footage which compromises the quality of the video.

![A and B](Figure 1.png)

**Figure 1.** Snapshot from video footage for (a) open expressway and (b) tunnel expressway

### 4.2. Data extraction

A manual frame-by-frame approach is used for data extraction. Manual data extraction is performed for two reasons. First, the traffic cameras do not have sufficient height to provide an ideal plan view of the traffic. As a result, automated image processing/computer vision will not be able to detect vehicles properly. Second, existing automated methods are also unable to provide accurate vehicle classifications.

Two reference lines are marked over the video image and the distance between the two lines can be determined using the lane markings. The timestamps (with a resolution of 0.04 s) at which a vehicle passes each of the two reference markings are logged, along with the vehicle class (motorcycle MC, car, light goods vehicle LGV, or heavy vehicle HV) and the lane travelled. Rear-to-rear headways are used in this study instead of the frontal headways (see Figure 2). In rare instances where the view of a vehicle is obscured, the
timestamps are estimated by the observer. This video extraction approach had been validated in several traffic studies (Meng and Weng, 2011; Meng and Qu, 2012) and it was reported to effectively yield data of comparable quality to those obtained using the radar-speed measurement method (Strong et al., 2003).

![Figure 2. Illustration of headway, gap, and rear-to-rear headway](image)

### 4.3. Treatment of lane splitting MC

Lane splitting MC refers to a MC that travels in between traffic lanes (or in the case of exterior lanes, a MC that travels at the edge of the traffic lanes). It is assumed in this study that these MCs do not affect within-lane car following behaviour in any significant way and are excluded from the analysis.

### 4.4. Identification of car following instances

Several studies used a critical headway approach to characterise car following (Sayer et al., 2003; Brackstone et al., 2009; Shiomi et al., 2011). These studies only considered headways smaller than a defined threshold to represent car following, while headways longer than the threshold are disregarded. However, critical headways are not suitable for application in this study due to several reasons. First, there is no evidence that the same critical headway applies to both open and tunnel road environments. Second, there is no evidence that the same critical headway applies to all vehicle classes, especially when heterogeneous traffic is being examined. Third, the study objective is to examine how various factors affect car following and most of the measures will be derived from headways. By truncating the data based on headways, the results will be biased towards behaviour at smaller headways even though some drivers may choose to adopt larger headways in certain situations.

Instead, all headways are considered in this study and categorised by speed. When vehicle speed is lower than the imposed speed limit, it is reasonable to assume that the vehicle is experiencing some level of
impedance and is in car following mode. Furthermore, since the data are collected during the peak hours, the occurrence of non-car following instances would be minimal.

4.5. Assessment of headways

With the timestamps of two successive vehicles $t_n$ and $t_{n-1}$ (n represents the order of the vehicle), the time headway $THW_n$ (refer to Figure 1) and vehicle speed $v_n$ can be determined:

$$THW_n = t_{n,L1} - t_{n-1,L1}$$

$$v_n = D/(t_{n,L2} - t_{n,L1})$$

where $n$ refers to the vehicle identification (assigned by the order of appearance), $L1$ the upstream reference line, $L2$ the downstream reference line, and $D$ the distance between the two reference markings. The length of $D$ used in this study is 14 m. Car-X (follower-leader, X denotes any vehicle class) headways are extracted from the entire dataset for analysis.

Data from both road environments are assessed using ANOVA to investigate whether the road tunnel environment has significant effects on headways. However, the data used in the ANOVA will depend on the data availability in various cells and consideration for the significance of underlying factors affecting headway choice. For this reason it is essential to identify these factors first.

The effects of speed, lane, and leader type are assessed using ANOVA in the first analyses.

4.6. Assessment of TTC

TTC is defined as the time taken for a collision to occur given that the vehicles of interest maintain their current states of motion which will result in a collision. Again, only TTC for cars as followers are considered. In order to determine TTC, the gap between vehicles is first obtained. The distance gap $DX$ between two vehicles is determined by:

$$DX_n = THW_n \cdot v_n - l_{car}$$

where the average car length $l_{car}$ is taken to be 4.5 m. TTC is then estimated using:

$$TTC_n = \begin{cases} 
\frac{DX}{DV} = \frac{DX}{v_n-v_{n-1}}, & v_n > v_{n-1} \\
N.A., & otherwise
\end{cases}$$

where TTC values are only existent in gaps where the follower’s speed is greater than the leader’s speed. If the leader is travelling faster than the follower, a collision is rendered impossible.
The data points used in Bifulco et al. (2013) were experimentally determined action points. However, the data points used in this observational study represent any point in the car following spirals and not necessarily the action points. Nonetheless, these data points would be statistically spread symmetrically around the mean slope. Hence, a regression analysis of the slope will, in theory, produce a similar coefficient as compared to using action points only, with the main difference being a lower $R^2$ due to the further spread of data points around the regressed slope.

4.7. Assessment of SM

The determination of SM is given as:

$$SM = 1 - \left\{ \frac{0.15v_n}{DX} + \frac{[v_n+v_{n-1}][v_n-v_{n-1}]}{1.5gDX} \right\}$$

(5)

where $g$ is the acceleration due to gravity. For its theoretical development and mathematical formulation, refer to Lu et al. (2012). The SMs for cars in each road environment will be evaluated and the mean SM represents the desired SM of the drivers in the road environment. Furthermore, safety is ensured when

$$\frac{v_nT_1}{DX} \leq SM$$

(6)

where $T_1$ represents the driver response time, which is assumed to be one second. According to studies on driver brake reaction time (Warshawsky-Livne and Shinar, 2002; Makishita and Matsunaga, 2008), the average brake reaction time is close to one second.

The likelihood of ensured safety is also determined to evaluate traffic safety based on car following. For each car following instance, equation (6) is applied to determine whether safety is ensured. The likelihood is then derived as the proportion of car following instances (car as followers) where equation (6) is satisfied.

All statistical procedures are performed using IBM SPSS 21.

5. Results

Due to the data available being greatly unbalanced, full factorial ANOVA cannot be performed to assess the effects of lane, speed, and leader type, in each road environment. As a result, piecewise evaluation of the factors using ANOVA is performed instead and careful inferences are made. In essence, seven ANOVAs (A through G) are performed.

$THW$ is observed to follow a lognormal distribution across the groups. In order to utilise ANOVA, $THW$ is first treated with natural log transformation into $log \ THW$. In addition, continuous speed data are also
categorised into speed bands of 10 kph, indicated by their mid-point values, i.e. data falling between speed of 50 and 60 kph will be classified as 55 kph.

In addition to \( THW \), the analyses are repeated using distance headways (a through g, corresponding to A through G). Similarly, distance headways are observed to follow a lognormal distribution and natural log transformation is applied.

### 5.1. Open expressway

A total of 11,167 vehicles are observed for the open expressway condition. The traffic composition is presented in Table 1. For the three-lane expressways, Lane 1 is the fast lane, Lane 2 is the middle lane, and Lane 3 is the slow lane.

Table 2 presents a summary of the results from the various ANOVAs (A through D; a through d) for open expressway, using both the log-transformed time and distance headways. The mean time headways of groups evaluated in the ANOVAs for open expressway are illustrated in Figure 3, while the mean distance headways are illustrated in Figure 4.

#### 5.1.1. Effect of speed on headways

To control for the effects of leader type and lane, four ANOVAs (A, B, a, and b) are conducted. The ANOVAs find a consistent effect of speed on both time and distance headways. Post-hoc comparisons in ANOVAs A and B find time headways to be the shortest at 65 kph (see Figure 3). Post-hoc comparisons in ANOVAs a and b find distance headways to increase with speed (see Figure 4).
5.1.2. Effect of leader type on headways

Controlling for effects of speed and possible effects of lane, two ANOVAs (C and c) are conducted. Car-MC pairs are not considered due to their small sample size. Both ANOVAs are consistent in finding no significant effect of leader type. However, significant effect of speed is found on distance headways but not on time headways. The interaction term speed*leader type is not found to be significant in both cases.

5.1.3. Effect of lane on headways

ANOVAs D and d effectively control for effects of speed and possible effects of leader type. Both ANOVAs find significant effects of lane and speed, while no significant interaction effects of speed*lane are found. Post-hoc comparisons find both time and distance headways to be shortest in Lane 1 and longest in Lane 3.

5.2.1. Effect of speed on headways in tunnel

To control for the effects of leader type and lane, two ANOVAs (E and e) are conducted. The ANOVAs find a consistent effect of speed on both time and distance headways. Post-hoc comparisons in both ANOVAs find headways to increase with speed.

5.2.2. Effect of leader type on headways in tunnel

Controlling for effects of speed and possible effects of lane, two ANOVAs (F and f) are conducted. Both ANOVAs are consistent in finding significant effect of leader type. Post-hoc comparisons find that both time and distance headways are largest for Car-HV (follower-leader), followed by Car-LGV, Car-Car, and then Car-MC.

5.1.3. Effect of lane on headways

ANOVAs G and g effectively control for effects of speed and possible effects of leader type. Both ANOVAs find significant effects of lane and speed. Near-significant effect of the interaction term speed*lane is found in ANOVA G while significant interaction effect is found in ANOVA g. Post-hoc comparisons find both time and distance headways to be shortest in Lane 1 and longest in Lane 3.

Figure 5. Mean time headways evaluated for tunnel expressway
5.3. Comparison of headways between open and tunnel expressway

Taking into consideration the data available and the significance of the factors affecting headways in each road environment, two three-way ANOVAs (one for time headway and one for distance headway) are performed for time and distance headways for Car-Car pairs at speeds of 55 and 65 kph (2 speeds x 3 lanes x 2 environments). Table 5 presents the ANOVA results.

In both ANOVAs, significant effects of speed, lane, and environment are found. The interaction terms speed*lane, lane*environment, speed*environment, and speed*lane*environment are found to be significant as well. In the tunnel environment, greater increases in headways are observed in the slower lanes and with increasing speeds.

5.4. Comparison of TTC measures

Car following charts are produced in the –DV/DX vs. DV plane (opening chart), for both the open and tunnel expressways. Regression analysis is then performed for both set of data points, with the regression lines set to pass through the origin. Figure 7 illustrates the opening chart and Table 6 summarises the regression results obtained.

![Figure 7. Opening chart for open and tunnel expressways](image-url)

<td>(-0.029, -0.027)</td>
</tr>
</tbody>
</table>

The regression coefficients obtained are significantly different from each other. For the same closing relative speeds (-DV), the TTC-inverse (DV/DX) is very likely to be higher in open expressways than in tunnel expressways, i.e. TTCs are lower in open expressways. The average closing relative speeds in the open and tunnel expressways are -1.24 m/s and -1.62 m/s, respectively. When the average relative speeds are applied to the regressed model, a somewhat higher TTC value is obtained for tunnel expressway (22.09 s) as compared open expressway (21.75 s).

5.5. Comparison of SM and ensured safety

The SM values are analysed on a lane basis, since earlier findings revealed lane effects. Also, the likelihood of ensured safety is computed. Table 7 presents the results.

The mean SMs in the tunnel expressway are slightly higher than those in the open expressway. As for the likelihood of ensured safety, it is found that Lane 1 (fast lane) has the lowest likelihood of ensured safety while Lane 3 (slow lane) has the highest likelihood. It should be noted that the likelihood of ensured safety is consistently higher in the tunnels.

6. Discussion

The data are collected during peak hours from two sites that shared similar traffic compositions and average speeds. This section discusses the results and highlights the significant implications of the findings.
6.1. Factors affecting headway

The first part of the study identifies factors that have effect on car following headways. Car following patterns in open and tunnel expressways have been independently examined, using ANOVA for both time and distance headways. Factors considered include speed, leader type, and lane.

It is expected for distance headways to increase with speed due to longer braking distances at higher speeds. Taieb-Maimon and Shinar (2001) and Duan et al. (2013), based on experimental data, reported differences in distance headway at different speeds but insignificant differences in time headway. If time headways do not differ across speeds, it would imply that a driver’s perceived risk in car following is mainly a function of the driver’s perceived reaction time and that distance headway is merely the product of speed and the desired time headway. However, the findings in this study provide evidence that speed has a significant effect on time headway, which implies that drivers’ perceived risk changes with speed. This will be discussed later with the comparison of headways with other studies.

The absence of speed effects in the experimental studies may be due to Hawthorne effect, an impact on behaviour due to the awareness of being studied. As discussed by Boer (1999) and Hancock (1999), driving is generally a satisficing task. Under normal driving situations, drivers behave in a manner well enough to meet their driving goals and do not seek to optimise their behaviour. In an experimental context, drivers may have unknowingly performed in an optimising manner. Naturalistic observations thus offer higher fidelity (Eby, 2011).

The lane travelled is also found to be a significant factor in both road environments. Consistent in both environments, headways in Lane 1 (fast lane) are the shortest while headways in Lane 3 (slow lane) are the longest. Lane effects are not unexpected – when lane speeds are similar with that in the other lanes, “faster” vehicles in the fast lane may somewhat create the illusion of speed by travelling at shorter headways. The lane effects agree with the findings of (Olcott, 1955), who found that the fast lane had a different speed-density curve from the slow lane in the Lincoln Tunnel. A possible explanation for lane effect is that, in a traffic culture where lanes are associated with different speeds, drivers who opt to stay in the slow lane would be more conservative than those in the fast lanes. The higher overall level of risk aversion in the slower lanes thus results in longer headways. If true, this has interesting implications on future research which may identify different driver groups (in terms of risk perception) based on lanes.
The effect of leader type is found to be significant in the tunnel expressway but not significant in the open expressway. In the tunnel, car drivers maintained longer headways behind larger vehicles. Intuitively, one would expect longer headways when following behind larger vehicles due to the view of the road ahead being obscured, adding elements of uncertainty to the drivers’ perceived risk. However, in the open expressway drivers seem to disregard the leader type. Perhaps the obscuration of the road ahead has a greater effect in the tunnels due to limited sight distances. Various studies had examined the effect of leader vehicle type but conflicting findings had been obtained. While Puan (2004) and Duan et al. (2013) observed larger headways behind trucks than cars, Ossen and Hoogendoorn (2011), Brackstone et al. (2009), and Sayer et al. (2003) observed the opposite. They reasoned that since trucks have lower braking power which results in longer braking distance, car drivers following behind them have more time and distance to react and hence are able to maintain shorter headways. On the other hand, Yousif and Al-Obaedi (2011) found no differences in car headways behind cars or trucks. With regard to the inconsistency in the various studies, it would appear that environmental and cultural factors play an important role.

Overall, after controlling for speed, lane, and leader type, headways (both time and distance) are longer in the tunnel than in open expressways. The road environment also has significant interaction effects with the mentioned factors. The findings in this study provide behavioural evidence that drivers indeed perceive higher risks in the tunnel environment (hence maintaining relatively larger headways). This is consistent with perception studies in the literature (Serrano and Blennemann, 1992; Arias et al., 2008), where drivers were found to perceive road tunnels as hostile environments and experience unpleasant feelings while driving in tunnels. It is also possible that drivers perceive driving in tunnels as a novel experience and hence drive more conservatively (Lemke, 2000). However, based on the free association study by Yeung et al. (2013), drivers did not associate tunnels with novelty effects or unfamiliarity. Instead drivers associated more strongly with lighting, safety, and enforcement. This implies that novelty effects are insignificant and environmental effects are inherent.

Another possible explanation for the more conservative car following behaviour in tunnels is the presence of traffic cameras. A characteristic of urban road tunnels is the high density of traffic cameras to monitor traffic throughout the tunnel, unlike open roads where traffic cameras are further apart. Drivers may adopt more “sociable” driving behaviour in tunnels due to the awareness of being monitored. However, this
explanation is less likely to be true because behavioural differences have been demonstrated in simulator studies where the effect of traffic cameras is non-existent.

6.2. Comparison of headways with other studies

The Car-Car distance headways in this study are compared to minimum safety distances and the two-second rule (see Figure 8). In the derivation of safety distances, driver reaction time is assumed to be one second, and the deceleration term coefficient (reciprocal of twice the maximum average deceleration of a following vehicle) adopted is $0.075 \text{s}^2/\text{m}$, as suggested by Rothery (2011) for the case when the leading vehicle comes to a full stop instantaneously. In the less conservative set of safety distances, the deceleration term is assumed to be absent, i.e. the following vehicle adjusts its deceleration synchronously with the leading vehicle. In addition, comparison is done with results from other studies (Brackstone et al., 2002; Puan, 2004).

![Figure 8. Comparison of car following behaviour](image)

The headways in this study, like those found in other studies, mostly fall between the conservative and less conservative safety distances. The minimum safety distances and two-second rule considers only the crash likelihood based on consistent driver reaction and braking times, i.e. constant time headway. The headways observed in this study are shown to become more conservative as speed increases. This can be explained by the higher perceived risk at higher speeds. If a consistent driver reaction time is assumed (controlling for crash
likelihood), it is possible that perceived crash consequence is more severe at higher speeds. Higher speeds are associated with greater crash severity and higher crash rates (Aarts and van Schagen, 2006). As shown in Figure 8, headways in road tunnel are the highest, which is explained by higher perceived risk in the road tunnel environment. However, headways at speeds above 65kph should be interpreted with caution due to the 70 kph speed limit of the tunnel being observed in this study.

6.3. Rear-end collision risk

Headways indicate the potential danger while TTCs indicate actual danger (Vogel, 2003). Time-to-collision values in both road environments were assessed using car following waves. The results, as shown in Figure 7, indicate that for the same relative speeds, TTC values will be larger in the tunnel. This is because of the overall longer headways in the tunnel. Safety margins in the tunnel expressway are higher than those in the open expressway. The mean SM found in this study are consistent with those of Lu et al. (2012), who found mean SM values for professional and general drivers to be 0.862 and 0.896, respectively. This study shows that drivers desire higher safety margins in the road tunnel environment, which is consistent with findings of strong associations to safety in road tunnels (Yeung et al., 2013).

The likelihood of ensured safety is also computed. The computation takes into account the vehicle speeds, speed differentials, distance gap, and driver reaction time. Notably, instances of ensured safety are more likely in the tunnels, supporting the hypothesis that traffic is safer in the road tunnel environment.

6.4. Implications of longer headways

Traffic capacity is a key consideration for major roads with high traffic demand. Yeung et al. (2013) found that drivers strongly associated open expressways with speed and traffic conditions. In fact, it is common for unsafe headways to be observed in expressways due to shorter commute times being prioritised over safety, especially in urban areas where commute time is a greater disutility.

The longer headways in road tunnels imply that traffic capacity is compromised. Although road tunnels are superior in terms of traffic safety, capacity is expected to be lower than that of open roads. Thus, implementation of URS should take into account the reduced lane capacities in road tunnels. In order to provide similar traffic capacities, road tunnels may require more lanes than surface roads. From a land-use perspective, road tunnels may be a less efficient use of space, compared to other uses for underground space such as shopping malls and warehousing. However, when considering the potential use of surface land, URS
remains an attractive option. From a transportation perspective, URS should ideally serve to supplement surface roads and not to replace them, at least in the near future.

7. Conclusion

This study assessed the car following patterns observed in both open and tunnel expressways. Speed, lane, and leader type are found to have effects on headways to various extents. Overall, car following behaviour (with car as the follower) in the road tunnel environment is found to be more conservative (longer headways and greater safety margins) than that in the open road environment. The likelihood of ensured safety is also higher in the tunnels. Overall, from a microscopic behavioural perspective, traffic in tunnel expressways can be concluded to be safer than the conventional open expressways. The conclusion is consistent with the lower accident rates in road tunnels, suggesting that microscopic behavioural studies can serve as reliable traffic safety assessments. The effect of road environment is also discussed to be inherent.

With the increasing demand for urban space, URS is one of the proposed solutions. This study has shown that, in terms of traffic safety, road tunnels perform better than open roads. However, enhanced traffic safety implies that traffic capacity is compromised. This study provides useful insight into inter-vehicle interactions in road tunnels and also the implications of implementing URS’s in future road networks.

Acknowledgements

The tunnel traffic video footage is provided by the Land Transport Authority of Singapore. In particular, the authors would like to thank KPE OCC for facilitating the video extraction from the traffic surveillance cameras. This study is part of a research project, “Driver behavioural adaptation to underground road conditions”, which is jointly funded by the Nanyang Technological University Sustainable Earth Office and Centre for Infrastructure Systems.

The authors would also like to thank two anonymous reviewers for their comments which have helped to improve the manuscript.
