Enhanced efficiency of solution-processed small-molecule solar cells by incorporating gold nanospheres and nanorods into organic layers†

Xiaoyan Xu, Aung Ko Ko Kyaw, Bo Peng, Qingguo Du, Lei Hong, Hilmi Volkan Demir, Terence, K. S. Wong, Qihua Xiong and Xiao Wei Sun

The significantly enhanced performance by incorporation of Au nanoparticles in solution-processed small-molecule solar cells is demonstrated. Simultaneously incorporating Au nanospheres into the hole transport layer and Au-silica nanorods into the active layer achieves superior broadband absorption improvement in the device with a power conversion efficiency of 8.72% with 31% enhancement.

Solution-processed small molecule (SM) bulk heterojunction (BHJ) organic solar cells are emerging as a competitive alternative to widely studied polymer solar cells (PSC). A power conversion efficiency (PCE) higher than 8% has recently been reported due to the excellent solubility in organic solvents, broadband light absorption and good charge transport property of the solution-processed SM donor. Moreover, this type of SM donor offers simple synthesis, purification and monodispersity compared to polymeric materials. As with the PSC, SM solar cells are limited by insufficient light absorption because the short exciton diffusion length and low carrier mobilities of organic semiconductor materials necessitate the use of thin active layers. As a result, an approach to enhance light absorption without increasing the thickness of the active layer is necessary. Recently, metallic nanoparticles (NPs) have been widely introduced into PSC for enhanced light harvesting induced by the plasmonic effect of metallic NPs. In the literature, there are reports on plasmonic PSC in which single metallic NPs are incorporated into various layers, for examples: the hole transport layer (HTL), active layer or both. In addition, two different metallic NPs have been blended within a single layer. Despite significant PCE enhancement in PSC, there have been no reports on the plasmonic effect of metallic NPs in solution-processed SM solar cells. In plasmonic devices, the configuration that incorporates metallic NPs into the HTL layer and the active layer results in better hole transport and improved light absorption while the configuration that combines different shapes of NPs in the active layer achieved a broadband absorption enhancement. However, embedding NPs with two different shapes into the HTL layer and the active layer respectively, in order to leverage advantages of both configurations, has not been reported yet.

In this communication, we report high-performance solution-processed SM solar cells by incorporation of Au nanospheres into the poly(3,4-ethylene-dioxythiophene): poly(styrenesulphonate) (PEDOT:PSS) layer and Au-silica nanorods into the 7,7′-(4,4-bis(2-ethylhexyl)-4H-silolo[3,2-b:4,5-b′]-dithiophene-2,6-diy1)bis(6-fluoro-4-(5′-hexyl-[2,2′-bithiophen]-5-yl)benzo[1,2,5]thiadiazole):[6,6]-phenyl-C71-butyric acid methyl ester (p-DTS(FBTTh3):PC71BM) layer, simultaneously. Thus far, only a few reports studied the metallic nanorods with larger size which have a longer extinction wavelength to contribute a wide absorption spectrum enhancement up to 700 nm. These nanorods can give rise to both plasmonic and scattering effects. A combination of Au nanospheres and Au-silica nanorods in organic layers achieves a broader optical absorption enhancement and better hole transport. As a result, significantly improved PCE is realized by incorporating dual Au NPs.

Fig. 1a-d shows molecular structures of p-DTS(FBTTh3):PC71BM, SM device structure, and the transmission electron microscope (TEM) images of Au nanospheres and Au-silica nanorods, respectively. Au NPs were synthesized using the seed-mediated method. Au nanospheres had an average diameter of about 10 nm. Au-silica nanorods are completely and uniformly coated by 6 nm silica shell and have the average length and diameter of 89 nm and 34 nm respectively. The normalized UV-vis absorption spectra of Au nanospheres in water and Au-silica nanorods in chlorobenzene (CB) were measured. Fig. 1c shows that the maximum absorption peaks of Au nanospheres and Au-silica nanorods were at 521 and 681 nm, respectively. Here, four types of SM solar cells were fabricated (Device A: reference device without NPs; B: Au nanospheres in PEDOT:PSS only; C: Au-silica nanorods in the active layer only; D: NPs in both PEDOT:PSS and the active layers). The atomic force microscopy (AFM) images of the PEDOT:PSS layer and the active layer in Fig. S1, show that the root-mean-square (RMS) roughness of PEDOT:PSS films increases from 0.872 nm to 0.899 nm and that of the p-DTS(FBTTh3):PC71BM films increases from 1.677 nm to 1.840 nm when incorporating NPs. The almost unchanged RMS roughness confirm that all the NPs are embedded within PEDOT:PSS layer and the active layer and would not affect their morphologies.
The maximum conversion efficiency (PCE) was 13.53 ± 0.36 % in the reference device and 14.95 ± 0.37 % in device with dual NPs. The improvement in PCE is due to the increased short-circuit current density (JSC) and fill factor (FF). The JSC in the reference device is 12.17 ± 0.32 mA cm⁻², whereas the JSC in the plasmonic device is 15.56 ± 0.37 mA cm⁻², which is an increase of 0.34 ± 0.09 mA cm⁻². The FF in the reference device is 0.77 ± 0.01, whereas the FF in the plasmonic device is 0.71 ± 0.02, which is an increase of 0.01 ± 0.01. These improvements are due to the increased light absorption and transmission of the plasmonic device.

To verify that the improved JSC is due to optical effect of Au NPs, we performed the UV-vis absorption and the incident photon to current conversion efficiency (IPCE) measurements. Fig. 2b, c shows that the absorption and IPCE spectra of the active layer are both enhanced in the spectral region of 420 to 550 nm after incorporation of Au nanospheres only in PEDOT:PSS layer, and further improvement in the spectral range of 460 to 720 nm are evident after incorporation of Au-silica nanorods only in the active layer. In addition, the broader light absorption and IPCE spectra covering from 420 to 720 nm are achieved when combining dual Au NPs in the devices. Such enhanced absorption and IPCE spectra are well matched with the plasmonic resonance region of Au nanospheres and Au-silica nanorods.

To further confirm the effect of Au NPs on the optical absorption of the SM solar cell, we determined the maximum photoinduced carrier generation rate (Gmax) in devices with and without dual NPs. Fig. 2d shows the dependence of the photocurrent density (Jph) on the internal voltage (Vin) for reference and plasmonic devices. Jph is determined as Jph = Jl - J0, where Jl and J0 are the current density under illumination and in the dark, respectively. Vint is calculated as Vint = Vin - V0, where V0 is the voltage at which Jph = 0 and Vint is the applied voltage. Fig. 2d shows that Jph increases linearly at low Vint and saturates at a high Vint (2 V and above), which is large enough to dissociate all the photogenerated excitons into free charge carriers and collect them at the electrodes. Thus, at a high Vint, saturation current density (Jsat) is only limited by the total number of absorbed photons. Gmax could be calculated from Jsat = qL2Gmax, where q is the electronic charge and L is the thickness of active layer. The value of Gmax for the reference device and plasmonic device are 8.43 × 10²⁷ m⁻³ s⁻¹ (Jsat = 135 A m⁻²) and 1.07 × 10²⁸ m⁻³ s⁻¹ (Jsat = 172 A m⁻²), respectively. A significant enhancement of Gmax occurred after incorporating dual Au NPs. Since Gmax corresponds to the maximum number of absorbed photons, such enhancement demonstrates increased light absorption in device with dual NPs.

The mechanisms of enhanced light absorption by Au NPs are studied by finite-difference time-domain (FDTD) method and diffuse scattering measurements.5 Fig. 3a shows the distribution of electric field around the Au-silica nanorods at 680 nm. It is found that the electric field is increased by a factor of 2 relative to the incident light outside the silica shell which will increase absorption within the active layer. Moreover, the haze factor spectra for transmission (Ht) and reflection (Hr) are measured by dividing the
diffuse transmission/reflection by the total transmission/reflection. Fig. 3 shows the increase in both $H_T$ and $H_R$ upon incorporating the Au-silica nanorods, suggesting that NPs scatter more light to increase the optical path. Therefore, both plasmonic and scattering effects excited by NPs contribute to light absorption in SM solar cell.

Fig. 4.a shows the charge collection probability ($P_c$) versus $V_{in}$. The $P_c$ could be obtained by normalizing $J_{ph}$ by $J_{sat}$. The $P_c$ under short-circuit condition ($V_{sc}$ = 0 V) increases from 88.1% to 91.3% by adding dual Au NPs, indicating that the incorporation of Au NPs has a positive influence on the charge collection by electrodes. The value of $P_c$ is higher than PSCs and it decreased slowly from short-circuit condition to open-circuit condition compared to sharp increase of polymer counterpart. This indicates that there is less recombination and thus result in high photocurrent and fill factor in p-DTS(FBTh$_3$)$_2$:PC$_{60}$BM device.

Since carrier mobility is an important factor for charge transport and mainly limited by the hole transport in our devices, only hole-only devices were fabricated to determine the hole mobility. The dark $J$-$V$ characteristics of hole-only devices are measured and fitted using the space-charge-limited current (SCLC) model and the Mott-Gurney law that includes field-dependent mobility, shown in Fig. 4b. Upon incorporation of Au NPs in the PEDOT:PSS layer only, active layer only and both layers, the zero field hole mobility slightly increased from 1.26 × 10$^{-3}$ cm$^2$ V$^{-1}$ s$^{-1}$ to 1.41 × 10$^{-3}$ cm$^2$ V$^{-1}$ s$^{-1}$, 2.07 × 10$^{-3}$ cm$^2$ V$^{-1}$ s$^{-1}$ and 2.28 × 10$^{-3}$ cm$^2$ V$^{-1}$ s$^{-1}$ respectively. An increase in the hole mobilities indicate that the incorporation of the Au NPs does not adversely affect the charge transport in the active layer.

In conclusion, we demonstrate the maximum PCE of 8.72% with a relative performance increase of 31% in solution-processed SM solar cell by incorporation of Au nanospheres and Au-silica nanorods into organic layers. Absorption spectra, IPCE spectra and $G_{max}$ confirm that the combination of Au NPs with two different shapes realized a broadband absorption improvement in the SM solar cells. The studied mechanisms of enhanced light absorption ascribe to both plasmonic and scattering effects by Au NPs. Enhanced carrier collection and carrier transport properties ensure the good performance in plasmonic device. Therefore, apart from contributing to light absorption within the active layer, the Au nanospheres in PEDOT:PSS layer can facilitate the hole collection and Au-silica nanorods in the active layer avoid the carrier recombination at the metal surface by insulating silica shell.
