An approach based on a non-Markovian time-convolutionless polaron master equation is used to probe the quantum dynamics of a chromophore-qubit in a super-Ohmic bath. Utilizing a measure of non-Markovianity based on dynamical fixed points, we study the effects of the environment temperature and the coupling strength on the non-Markovian behavior of the chromophore in a super-Ohmic bath. It is found that an increase in the temperature results in a reduction in the backflow information from the environment to the chromophore, and therefore, a suppression of non-Markovianity. In the weak coupling regime, increasing coupling strength will enhance the non-Markovianity, while the effect is reversed in the strong coupling regime.

I. INTRODUCTION

Recent advances in spectroscopic techniques have allowed increasing deployments of nonlinear optical measurements to probe dynamic properties of various condensed-matter and biological systems [1–16]. An interesting example from two-dimensional electronic spectroscopy studies is the conjecture that long-lasting quantum coherence may exist photosynthetic light harvesting systems [1–7]. Nonlinear single molecule spectroscopic techniques, such as hole-burning and three-pulse photon echo spectroscopy [12], capable to generate truly homogeneous lineshapes by eliminating inhomogeneous broadening, have been used to probe chromophores embedded in organic glasses, revealing a wide range of spectral behaviors, where the coupling of chromophores to the surrounding medium (solvent, glass, host crystal, protein, etc) may give rise to non-Markovian dynamics.

For low-temperature glasses and amorphous solids characterized by structural disorder, often only the two lowest energy levels of the double minimum potential need to be considered. Therefore, they can be modeled as a collection of two-level systems, and indeed such a model has been successfully employed to study their anomalous specific heat and thermal conductivity [17, 18]. With the local environment modeled as a collection of flipping qubits which modulate the chromophore transition frequency [19], Suarez and Silbey [20] proposed a microscopic Hamiltonian to study the dynamics of a single chromophore in glasses, and demonstrated its correlation with the stochastic sudden jump model [21]. Their dressed microscopic Hamiltonian is taken as our starting point to investigate the dynamics of a central chromophore embedded in a bath of qubits commonly found in low-temperature glasses.

In the aforementioned chromophore-qubit pair, the energy scales for the vibronic relaxation and spin-phonon coupling are comparable placing the system-bath interaction outside the usual weak coupling regime which is inaccessible to the traditional second-order perturbation methods [22–24]. Therefore, non-perturbative approaches [25–31], including the numerically exact iterative path integral methods [29], sophisticated stochastic treatments of the system-bath models [30], and hierarchical equation of motion approach [31], have subsequently been proposed to treat such systems of intermediate coupling. However, these computationally intensive methods is inadequate to deal with large systems or multiple-excitations. Recently, the non-Markovian time-convolutionless polaron master equation has been employed to describe the excitation dynamics in the multichromophoric systems [24, 32–36]. The advantage of this master equation is that it is capable of depicting the dynamics in intermediate coupling regimes, handling initial non-equilibrium bath states, as well as the spatially correlated environments. This method has been successfully applied to study the dynamics of two coupled pseudospins in contact with a dissipative bath and in addition, it was used to investigate the energy transfer of an extended spin-boson model by including an additional spin bath [36].

Open quantum systems may exhibit interesting non-Markovian features that have been drawing sustained attention [37–40], and may be responsible for novel phenomena in chemical systems, such as dynamics controlling in polymers [41] and transport enhancing in biosystems [42]. More importantly, different degrees of non-Markovian behaviors may bring about different physical phenomena. Thus, quantifying the non-Markovian behaviors will help gain a better understanding in the underlying systems. In addition, coherent control nowadays has been demonstrated over a large number of quantum
systems of different complexity. A precise definition and quantification of the non-Markovianity brings this quantity into the context of coherent control, allowing the researchers to consider it as a target variable. On-purpose manipulation of the non-Markovianity opens up fascinating perspectives on the optimization of energy and charge transport in open quantum systems by engineering their coupling to heat baths. Among various definitions of non-Markovianity that emerged [43–48], one of the earliest, widely-used definitions was proposed by Breuer, Laine and Piilo (BLP) [43], which is based on the decreasing monotonicity of the trace distance under the completely positive and trace-preserving operations. One intuitive physical interpretation of this monotonicity is that the information of distinguishability always flows from the system to reservoir in a Markovian process. For a non-Markovian dynamics, this monotonicity can be violated and the trace distance may increase during the dynamics, indicating that the information of distinguishability may flow back from the reservoir to system.

In this paper, we propose a new measure of non-Markovianity based on the aforementioned mechanism for systems with dynamical fixed points. If \( N \) is the number of the initial states one take for numerical calculation, then this measure has a \( \mathcal{O}(N) \) numerical advantage compared with the BLP measure. By solving the time-convolutionless polaron master equation of the chromophore-qubit pair, we find a fixed point for the chromophore dynamics. Utilizing the non-Markovianity measure based on this fixed point, we are allowed to quantify the non-Markovian behavior of the central chromophore. Furthermore, we analyze the effects of the temperature and the coupling between the chromophore and the qubit on the non-Markovianity, and it is found that the temperature can suppress the backflow of the information in our model. With respect to the effect of the chromophore-qubit coupling, the situation is more complicated with differing influences of the coupling on the non-Markovianity in different regimes. We will show that in the weak coupling regime, the increase of the coupling strength can enhance the non-Markovianity, while in the strong coupling regime, it will suppress the non-Markovianity. In addition, the non-Markovian behaviors of the chromophore-qubit pair and the corresponding quasi-particle after the polaron transformation are also investigated. It is found that the non-Markovian behavior vanishes after the polaron transformation due to the much reduced coupling between the dressed particle and the bath.

The paper is organized as follows. In Sec. II, we introduce the model and the time-convolutionless polaron master equation of the chromophore-qubit pair with additional discussion on dynamical fixed points of the chromophore. In Sec. III, we revisit the BLP non-Markovianity measure and propose a new measure based on the dynamical fixed points of the system. In Sec. IV, we apply the new measure to our model and discuss the non-Markovian behavior of the chromophore. Section V draws the conclusion of this work.

## II. MODEL AND DYNAMICS

Chromophore is a term that commonly refers to a certain moiety of a large organic molecule that gives rise to its optical absorption and fluorescence properties, such as the pi-conjugated double bonds between carbon atoms in carotenoids, or the chlorine-type macrocyclic ring complexed by magnesium in chlorophylls. In the context of our work, this term refers to an entire molecule when it is embedded in a host environment, such as a pigment molecule in crystalline (e.g., pentacene in p-terphenyl crystal) or amorphous materials (perylene in polyethylene). In either context, a chromophore can be simply modeled as a system with two electronic levels (the ground the excited state) whose transition frequency can be modulated due to its interaction with the host environment. In general, there can be more than two levels in the chromophore. However, non-Markovianity based on trace distance depicts the oscillating behaviors of the trace distance between two evolved states. It does not directly reflect the oscillating information of populations in each level. Thus, the assumption of two-level chromophore helps reveal the qualitative behavior of non-Markovianity. The Hamiltonian can be written as [13, 20, 49]

\[
H = \frac{\omega_0}{2} \sigma_{z0} + \frac{\epsilon}{2} \sigma_{z1} - \frac{\Delta}{2} \sigma_{x1} + \frac{a}{2} \sigma_{x0} \sigma_{x1} + \sum_k \omega_k b_k^\dagger b_k + \sum_k g_k \left( b_k^\dagger + b_k \right) \sigma_{z1}.
\]

Here \( \sigma_{z0} := \sigma_z \otimes \mathbb{1} \) and \( \sigma_{z1} := \mathbb{1} \otimes \sigma_z \) for \( i = x, y, z \) and \( \sigma_z \) is a Pauli matrix. The subscript 0 (1) represents the subspaces of chromophore (qubit). We have set \( \hbar = 1 \) in this Hamiltonian. \( \omega_0 \) and \( \epsilon \) are the transition frequencies. \( \Delta \) is the tunneling matrix element. The coupling strength between the chromophore and qubit is represented by the coefficient \( a \), which is related to the distance between the chromophore and qubit, as well as the spin orientation of the qubit. \( \sum_k \omega_k b_k^\dagger b_k \) is the Hamiltonian of the phonon bath, with \( b_k^\dagger, b_k \) the creation and annihilation operators, respectively. \( g_k \) represents the coupling between the qubit and the reservoir. The Hamiltonian (1) can be also obtained through a unitary transformation from a Hamiltonian in which the chromophore and the qubit
FIG. 1: Schematics of the model. The chromophore interacts with the reservoir indirectly via a probe qubit.

are not directly coupled, but both interact with a common reservoir [13, 20]. To facilitate dynamics calculation, we first perform a polaron transformation on the Hamiltonian (1). The generator of this transformation reads

$$U = \frac{1}{2} B \sigma_{z1},$$

where $B = \sum_k (g_k / \omega_k) (b_k^\dagger - b_k)$. It is easy to verify the identify that $\exp(U) = \cosh(B/2) + \sigma_{z1} \sinh(B/2)$. After the polaron transformation, the new Hamiltonian can be written as

$$\tilde{H} = e^{iU} H e^{-iU} = \tilde{H}_0 + \tilde{H}_1 + H_b.$$  

Here the effective quasi-particle Hamiltonian $\tilde{H}_0$ has the form

$$\tilde{H}_0 = \frac{\omega_0}{2} \sigma_{z0} + \frac{e}{2} \sigma_{z1} - \frac{\Delta}{2} \sigma_{z1} \Theta + \frac{a}{2} \sigma_{z0} \sigma_{z1} - \sum_k g_k^2 / 4 \omega_k.$$  

The bath Hamiltonian is unchanged as $H_b = \sum_k \omega_k b_k^\dagger b_k$ and the effective interaction Hamiltonian $\tilde{H}_1$ can be expressed by

$$\tilde{H}_1 = -\frac{\Delta}{2} [\sigma_{z1} (\cosh B - \Theta) + i a \sigma_{y1} \sinh B],$$  

where $\Theta = \langle \cosh B \rangle = \langle \exp B \rangle$, and $\langle \cdot \rangle$ denotes the thermal average. It is found that

$$\Theta = \exp \left[ -\frac{1}{2} \sum_k \left( \frac{g_k}{\omega_k} \right)^2 \coth \left( \frac{1}{2} \beta \omega_k \right) \right].$$  

Given a bath spectral density $J(\omega) = \sum_k g_k^2 \delta(\omega - \omega_k)$, $\Theta$ can be rewritten as

$$\Theta = \exp \left[ -\frac{1}{2} \int d\omega \frac{J(\omega)}{\omega} \coth \left( \frac{1}{2} \beta \omega \right) \right].$$  

Through out this paper, we consider the total initial state in the original basis as

$$\rho_{\text{tot}}(0) = \rho_c \otimes |0\rangle_q \langle 0|_q \otimes \rho_b,$$

where $\rho_c$ is the reduced density matrix of the chromophore, $|0\rangle_q \langle 0|_q$ denotes the spin “up” state of the qubit, and $\rho_b = \exp(-\beta H_b)/Z$ is the thermalized phonon state in the original representation before polaron transformation. Here $Z = \text{Tr} [\exp(-\beta H_b)]$ is the partition function and $\beta = 1/(k_b T)$, with $T$ the temperature and $k_b$ the Boltzmann constant. In the paper we set $k_b = 1$.

In the interaction picture, the time dependent interaction Hamiltonian can be expressed by $\tilde{H}_I(t) = e^{i(B_0 + H_b)t} H e^{-i(B_0 + H_b)t}$. After some algebra, we have

$$\tilde{H}_I(t) = -\frac{\Delta}{2} \left[ \sigma_{z1}(t) D(t) + \sigma_{z1}(t) D^\dagger(t) \right],$$  

in which the time dependent operator $\sigma_{z1}(t)$ reads

$$\sigma_{z1}(t) = e^{iH_0 t} e^{-iH_0 t} \sigma_{z1} e^{iH_0 t},$$

where $D(t) = \sum_k (b_k^\dagger e^{i\omega_k t} - b_k e^{-i\omega_k t} D(t)$. The time evolution of the effective Hamiltonian (4) can be solved using the time convolutionless polaron master equation [24, 36, 43]. In the polaron representation, assuming that $\rho_{\text{tot}}$ is the reduced density matrix of the quasi-particle, then the quantum master equation can be expressed by [24, 32, 33, 36]

$$\partial_t \rho_{\text{tot}}(t) + i \left[ \tilde{H}_0, \rho_{\text{tot}}(t) \right]$$

$$= -ie^{-iH_0 t} \text{Tr}_b \left\{ \left[ \tilde{H}_I(t), Q \rho_{\text{tot}}(0) \right] \right\} e^{iH_0 t},$$

$$- \int_0^t ds e^{-iH_0 t} \text{Tr}_b \left\{ \left[ \tilde{H}_I(s), Q \rho_{\text{tot}}(0) \right] \right\} e^{iH_0 t},$$

$$- \int_0^t ds \text{Tr}_b \left\{ \left[ \tilde{H}_I(s), Q \rho_{\text{tot}}(0) \right] \right\} e^{iH_0 t},$$

where

$$Q \rho_{\text{tot}}(0) = \rho_{\text{tot}}(0) - \text{Tr}_b [\rho_{\text{tot}}(0) \otimes \rho_b],$$

with $\rho_{\text{tot}}(0) = e^{iH_0 t} \rho_{\text{tot}}(0) e^{-iH_0 t}$ being the density matrix of the total ensemble in the polaron representation. The general definition of the operator $Q$ is given by [50]

$$Q \rho := \rho - \text{Tr}_b (\rho) \otimes \rho_b.$$  

Taking into account the initial state (8), one has

$$Q \rho_{\text{tot}}(0) = \rho_c \otimes \langle 0|_q \langle 0|_q \otimes \left( e^{B/2} \rho_b e^{-B/2} - \rho_b \right).$$  

In this model, with respect to the chromophore dynamics, it is found that $\rho_{c, \text{fix}} = |0\rangle_\text{c} \langle 0|_\text{c}$ is a dynamical fixed point, i.e., it does not evolve with the passage of time, for which we will give a short proof here. Taking $|0\rangle_\text{c} \langle 0|_\text{c}$ as the initial state of the chromophore, in the Schrödinger picture, we have

$$\rho_c(t) = \text{Tr}_q \left( e^{-i\tilde{H}I\tilde{H}} |0\rangle_\text{c} \langle 0|_\text{c} \otimes |0\rangle_\text{q} \langle 0|_\text{q} \otimes \rho_b e^{i\tilde{H}I\tilde{H}} \right),$$

where $\tilde{H}_I$ is the effective Hamiltonian.
where the trace is taken over the subspaces of the qubit and the environment. Based on the expression of $\tilde{H}$ and the fact that $|0\rangle$ is the eigenstate of $\sigma_z = |0\rangle\langle 0| - |1\rangle\langle 1|$, one can find that

$$\tilde{H}|0\rangle_c\otimes|0\rangle_q\otimes\rho_b = |0\rangle_c\otimes\tilde{H}_{qb} (|0\rangle_c\otimes\rho_b) \tilde{H}_{qb},$$

where $\tilde{H}_{qb} = \tilde{H}_{0qb} + \tilde{H}_1 + H_0$, and $\tilde{H}_{0qb} = \omega_p + \frac{1}{2}\sigma_z - \frac{1}{2}\sigma_{z1}\Theta + \frac{1}{2}\sigma_{z1} - \sum_k \frac{\Delta_k}{\omega_k}$. It should be noted that though the notations in this Hamiltonian seem similar to those in $H$, the operators in $H_{qb}$ are actually confined to the subspace of the qubit and the environment. Then Eq. (14) can be rewritten as $\rho_c(t) = |0\rangle_c\langle 0|_{\mathcal{T}r_{qb}(e^{-i\tilde{H}_{0qb}\cdot t})}|0\rangle_q\otimes\rho_b e^{i\tilde{H}_{0qb}\cdot t}$. Based on the cyclic permutation invariance of trace, it can be simplified as

$$\rho_c(t) = |0\rangle_c.$$

Thus, $|0\rangle\langle 0|$ is a dynamical fixed point of the chromophore. More generally, it is known that diagonal fluctuations cause pure dephasing, while the off-diagonal fluctuations are responsible for population transfer. In our scenario, there are no off-diagonal fluctuations in the chromophore-related Hamiltonian. As a result, the decoherence of the chromophore is pure dephasing and all the diagonalized states are fixed points. Dynamical fixed points, which are especially useful in the study of the coherence-free subspace, will be utilized in this work to construct a new measure of non-Markovianity.

### III. NON-MARKOVIANITY

To quantify the non-Markovian behavior, several measures have been proposed [43–48], among which the BLP measure [43] relates the non-Markovian behavior to the backflow information from the reservoir to the system. The BLP definition is based on the trace distance

$$D_{tr}(\rho_1, \rho_2) := \frac{1}{2} \text{Tr}|\rho_1 - \rho_2|,$$

where $|\rho\rangle = \sqrt{\rho} \rho \sqrt{\rho}$. For a single qubit, it is known that its density matrix can be expressed in the Bloch representation as

$$\rho = \frac{1}{2} (1 + r \cdot \sigma),$$

where $r$ is the Bloch vector and $\sigma = (\sigma_x, \sigma_y, \sigma_z)^T$ with $\sigma_{x,y,z}$ the Pauli matrices. In this representation, the trace distance can be reduced to the Euclidean distance between the Bloch vectors $[51]

$$D_{tr}(\rho_1, \rho_2) = \frac{1}{2} ||r_1 - r_2||.$$ 

Here $||\cdot||$ is the Euclidean distance. $r_1$ and $r_2$ are the corresponding Bloch vectors of $\rho_1$ and $\rho_2$, respectively.

The trace distance is monotonous when the system goes through the quantum channels, which can be described by the completely positive and trace-preserving maps. Physically, this monotonicity is explained intuitively by that the information of distinguishability always flows from the system to the environment when the system goes through a quantum channel. Thus, the backflow of the information can be treated as a non-Markovian behavior, or a memory effect in which the environment absorbs information from the system and return some back to it, improving the distinguishability of the system. The BLP non-Markovianity is defined based on such a mechanism:

$$\mathcal{N}_{BLP} := \max_{\rho_{1,2}(0)} \int_{t, \rho > 0} dt \sigma (t, \rho_{1,2}(0)),$$

where

$$\sigma (t, \rho_{1,2}(0)) := \frac{d}{dt} D_{tr} (\rho_1(t), \rho_2(t))$$

is the time derivative of the trace distance during the evolution. The maximum is taken over all pairs of initial states $\rho_1(0)$ and $\rho_2(0)$. According to the definition, it can be found that $\mathcal{N}_{BLP} \geq 0$. For a Markovian process, the non-Markovianity is zero, i.e., $\mathcal{N}_{BLP} = 0$.

Dynamical fixed points may adopt various forms in physical systems, including states that are thermalized and ones within a decoherence-free subspace of a quantum system [52–55]. An alternative definition of non-Markovianity is introduced below based on the trace distance in the presence of dynamical fixed points

$$\mathcal{N}_{fix} = \max_{\rho_{0}(0)} \int_{\rho_{fix} > 0} dt \sigma_{fix} (t, \rho(0)),$$

where

$$\sigma_{fix} (t, \rho(0)) := \frac{d}{dt} D_{tr} (\rho(t), \rho_{fix}).$$

Here $\rho_{fix}$ is the matrix for any dynamical fixed point, which satisfies the equation $\partial_t \rho_{fix} = 0$, and the maximum is taken over all the initial state $\rho(0)$. It is easy to verify that $\mathcal{N}_{fix} \geq 0$, and $\mathcal{N}_{fix} = 0$ for Markovian dynamics. The greater the value of $\mathcal{N}_{fix}$, the stronger is the non-Markovian behavior. However, the absolute value of non-Markovianity is in itself not meaningful as different dynamics or methods will show different amplitudes of oscillations. Eq. (21) can be treated as a special form of the BLP measure as they both rely on the same mechanism, i.e., monotonicity of the trace distance under the completely positive and trace-preserving maps. The value of $\mathcal{N}_{fix}$ may be equal or less than that of $\mathcal{N}_{BLP}$. However, most of the physical information is contained in the variation of the non-Markovianity, not its absolute value. Therefore, despite that $\mathcal{N}_{fix}$ does not contain as many pairs of initial states as $\mathcal{N}_{BLP}$, it is still capable to describe the system behavior.

Moreover, compared with BLP measure, the $\mathcal{N}_{fix}$ measure has a numerical advantage. In principle, there are
an infinite number of states in the Hilbert space. To carry out the numerical calculation of Eq. (19), one has to sample a finite number of them. Assuming that this number is $N$, to take over all pairs of initial states, it generally requires $N(N - 1)/2$ times of calculations. Utilizing Eq. (21), the calculation number is only $N$. Therefore, for some complex dynamics with fixed points in it, Eq. (21) provides an efficient algorithm with a $O(N)$ numerical advantage.

Since the maximization in $N_{\text{fix}}$ is not taken over all pairs of initial states in the Hilbert space, this measure does not capture the full information on non-Markovianity. This incompleteness of information on non-Markovianity is a trade-off of numerical advantage. However, since the non-Markovianity is a property of system dynamics, it should be independent of the initial states in principle. As a matter of fact, dynamics can be called non-Markovian dynamics if the trace distance of any two states has the increasing behavior during the evolution. Thus, the size of the set in which the maximization is performed is not a decisive factor on the issue of non-Markovianity. Admittedly, Eq. (21) does not give a maximizing set as large as that of the BLP measure. We take a dynamical fixed point as the datum line being the maximization is performed is not a decisive factor on the issue of non-Markovianity. Admittedly, Eq. (21) does not give a maximizing set as large as that of the BLP measure. We take a dynamical fixed point as the datum line.

We then calculate the trace distance between this fixed point and all the states in Hilbert space, indicating that the dynamical information of all initial states are involved in this measure. This explains why Eq. (21) is capable to quantify the behaviors of non-Markovianity. Nevertheless, in some extreme mathematical cases where the numerical advantage of Eq. (21) is not obvious, the BLP measure would be a better choice.

As we discussed in Sec. II, the state $\rho_{c, \text{fix}} = |0\rangle\langle 0|$ is a dynamical fixed point of the chromophore. Thus, it is convenient to use Eq. (21) in our model to describe the non-Markovian behavior of the chromophore. In this section, we will apply the non-Markovianity measure (21) in the model given in Sec. II. With this measure, we further discuss the non-Markovian behavior of the chromophore, as well as the chromophore-qubit pair, in the presence of the phonon bath. The effects of the temperature and the coupling strength between the chromophore and qubit on the non-Markovianity will be discussed.

Generally, the expectation value of an observable $A$ of the chromophore-qubit pair can be written as $\langle A \rangle = \text{Tr}_{\text{cqb}} [\rho_{\text{tot}}(t)]$, where $\rho_{\text{tot}}(t)$ is the total density matrix in the original representation including the chromophore, the qubit and the phonon bath. The subscripts $c$, $q$ and $b$ represent the subspaces of the chromophore, the qubit and the bath, respectively. Using the inverse polaron transformation and inserting $P + Q$ into the expression, one can obtain the expectation of $A$ as [24, 36]

$$\langle A \rangle = \langle A \rangle_{\text{rel}} + \langle A \rangle_{\text{irrel}},$$

where $\langle A \rangle_{\text{rel}}$ is the relevant part, which can be written as

$$\langle A \rangle_{\text{rel}} = \text{Tr}_{\text{cq}} \left[ \tilde{\rho}_{\text{cq}}(t) \text{Tr}_{\text{b}} \left( e^{U \rho_{\text{b}}} e^{-U} \right) \right],$$

and the irrelevant part $\langle A \rangle_{\text{irrel}}$ reads

$$\langle A \rangle_{\text{irrel}} = \text{Tr}_{\text{cqb}} \left[ e^{U \rho_{\text{b}}} Q \rho_{\text{tot}}(t) e^{-U} Q \right].$$

When $[A, U] = 0$, the irrelevant part can be simplified into $\langle A \rangle_{\text{irrel}} = \text{Tr}_{\text{b}} \left[ A \rho_{\text{tot}}(t) \right]$. From the definition of $Q$ in Eq. (12), it is easy to see that $\text{Tr}_{\text{b}}[Q\rho_{\text{tot}}(t)] = 0$. Thus, for those observables that commute with the generator of the polaron transformation, their expectations contains only the relevant part, i.e.,

$$\langle A \rangle = \text{Tr}_{\text{cq}} [A \tilde{\rho}_{\text{cq}}(t)].$$
A. The chromophore

With above preliminary knowledge, we will try to reproduce the dynamical information of the chromophore in the original basis. For the chromophore-qubit pair, its density matrix in the original basis can always be decomposed into the form [56, 57]

\[ \rho_{cq} = \frac{1}{4} (\mathbb{1} + r_c \cdot \sigma_0 + r_q \cdot \sigma_1 + m \cdot \sigma_m), \]

where \( r_c \) and \( r_q \) are the Bloch vectors of the chromophore and qubit, respectively, while \( \sigma_i = (\sigma_{xi}, \sigma_{yi}, \sigma_{zi})^T \) for \( i = 0, 1 \), and \( \sigma_m = (\sigma_x \otimes \sigma_x, \sigma_y \otimes \sigma_y, \sigma_z \otimes \sigma_z)^T \). Through some straightforward calculation, one can find

\[ r_c = (\langle \sigma_{x0} \rangle, \langle \sigma_{y0} \rangle, \langle \sigma_{z0} \rangle)^T, \]

where the expectation \( \langle \sigma_{i0} \rangle = \text{Tr}_{cq}(\sigma_{i0} \hat{\rho}_{cq}) \) for \( i = x, y, z \). As \( [\sigma_{i0}, U] = 0 \), based on Eq. (26), the expectation of \( \sigma_{i0} \) in original representation is the same as that in the polaron representation, namely,

\[ \langle \sigma_{i0} \rangle = \text{Tr}_{cq} [\sigma_{i0} \hat{\rho}_{cq}(t)]. \]

In this way, we can reproduce the dynamical information of the chromophore. Using the expression of Bloch vector \( r_c \), the trace distance between \( r_c \) and the fixed point \( r_{c, \text{fix}} \) can be written as

\[ D_{tr} = \frac{1}{2} \sqrt{\langle (1 - \langle \sigma_{x0} \rangle)^2 + \langle \sigma_{x0} \rangle^2 \rangle + \langle \sigma_{y0} \rangle^2}. \]

The equivalent expression using the elements of the density matrix is

\[ D_{tr} = \sqrt{\rho_{c22}^2(t) + |\rho_{c,12}(t)|^2}. \]

Substituting this equation into Eq. (21), the fixed-point non-Markovianity can be obtained as

\[ N_{\text{fix}} = \max_{\rho(0)} \int_{\sigma_{\text{fix}} > 0} \sigma_{\text{fix}} dt, \]

with

\[ \sigma_{\text{fix}} = \frac{1}{D_{tr}} (\rho_{c,22}(t) \partial_t \rho_{c,22}(t) \]

\[ + |\rho_{c,12}(t) \partial_t |\rho_{c,12}(t)|). \]

Figure 2 displays the time evolution of the trace distance of the chromophore. The initial states are chosen as \( r_{c1} = (1, 0, 0)^T \) and \( r_{c, \text{fix}} = (0, 0, 1)^T \). Here \( r_{c, \text{fix}} \) is the Bloch vector of the dynamical fixed point of the chromophore: \( \rho_{c, \text{fix}} = |0\rangle \langle 0| \). The parameters are set as \( \epsilon = \omega_0, \Delta = 0.8\omega_0, a = 2\omega_0, \) and \( T = 0.5\omega_0 \). A super-Ohmic spectral density \( J(\omega) = \kappa \omega_0^{-2} \omega^3 \exp(-\omega/\omega_c) \) is taken with the characteristic phonon frequency \( \omega_{ph} = \omega_c \), the cutoff frequency \( \omega_c = 4\omega_0 \), the coupling strength \( \kappa = 0.1\omega_0 \). The red solid line in Fig. 2 is the result from

the time convolutionless master equation. As a comparison, we also display the corresponding dynamics of the trace distance from the Redfield equation. It is found in Fig. 2 that utilizing the time convolutionless master equation, the trace distance has an oscillating component in its evolution, while it is monotonously decreasing using the Redfield theory. This monotonicity exists for any initial state, indicating vanishing non-Markovianity, which is agreement with the fact that dynamics governed by the Redfield equation is Markovian. For the time convolutionless master equation, the descending trend of the trace distance is due to the dissipative effect of the environment, indicating an information flow from the system to the environment. However, this information flow is by no means unidirectional. The oscillation of the trace distance demonstrates the back flow of information from the environment to the system, pointing to the non-Markovian behavior in the dynamics of the chromophore.

As part of the system-environment correlation, the non-Markovianity must be affected by the temperature of the environment, as discussed in the literatures [50, 58, 59]. Here we also examine the influence of temperature on the non-Markovianity. Figure 3 shows the behavior of non-Markovianity \( N_{\text{fix}} \) as a function of the temperature. The parameters in this figure are set as \( \epsilon = \omega_0, \Delta = 0.8\omega_0, \) and \( a = 4\omega_0 \). The spectral density and the relevant parameters are the same as those in Fig. 2. We have taken over more than 1000 initial states for each temperature point in this plot. Figure 3 demonstrates that the increase of the temperature can suppress the non-Markovianity.

To further probe the temperature effect, we plot the evolution of the trace distance with specific initial states \( r_{c1} = (1, 0, 0)^T \) and \( r_{c, \text{fix}} = (0, 0, 1)^T \), as shown in Fig. 4. It is found that the increasing temperature can speed up the decay of trace distance, as well as suppress its oscillation. More phonons are excited with the rise of
temperature, leading to the speed up of decoherence of chromophore via the probe qubit. The acceleration of the decoherence will reduce the oscillation amplitudes of the coherence of the density matrix of chromophore and increase its decay rate. Then, based on the equation \( D_{t_{1}}^{2} = \rho_{22}(t) + |\rho_{12}(t)|^2 \), one can see that the speed up of decoherence results in a faster decay of the trace distance, and its oscillating amplitude, causing a further reduction of non-Markovianity and therefore a suppression of the information backflow.

The calculation of the BLP measure for the system studied in our manuscript requires a computation time that is inaccessible, making impossible a direct comparison between the BLP non-Markovianity and the fixed-point non-Markovianity. However, some of our results are well in agreement with a number of earlier studies [50, 58, 59] of the BLP non-Markovianity that show a suppressed behavior with an increasing temperature. The fixed-point non-Markovianity is thus a compromised form of the BLP measure and is qualified to capture the non-Markovian behavior of dynamics in this system.

Another important parameter affecting the system-environment correlation is the coupling strength \( a \) between the chromophore and qubit, which is proportional to the angular orientation parameter \( \eta \) of the dipole-dipole interaction and inversely proportional to the cube of the distance \( r \) between the chromophore and qubit [13], i.e., \( a \propto \eta/r^3 \). In previous studies where the dynamical processes are solved by the perturbation methods, it is difficult to gauge the effect of the coupling strength on non-Markovianity due to the weak coupling constraint. In our cases, this constraint is reflected by the parameter \( \kappa \) in the spectral density, i.e., \( \kappa \) cannot be arbitrarily large. However, the coupling between the chromophore and qubit can be chosen in a wide range, without affecting the accuracy of the time-convolutionless master equation, allowing a study on the non-Markovianity in the strong coupling regime.

Figure 5 shows the variation of the non-Markovianity \( N_{\text{MK}} \), as a function of coupling parameter \( a \). Other parameters in this figure are set as \( \epsilon = \omega_0 \), \( \Delta = 0.8\omega_0 \), and \( T = 0.5\omega_0 \). The spectral density and the relevant parameters are the same as those in Fig. 2.

FIG. 5: The variation of non-Markovianity \( N_{\text{MK}} \) as a function of the normalized coupling strength \( a/\omega_0 \). The parameters in this figure are set as \( \epsilon = \omega_0 \), \( \Delta = 0.8\omega_0 \), and \( T = 0.5\omega_0 \). The spectral density and the relevant parameters are the same as those in Fig. 2.

FIG. 6: The time evolution of the trace distance with three values of the coupling strength \( a \). Left Panel: the red solid line, the black dashed dotted line and the blue dashed line represent the trace distances with \( a = 2\omega_0 \), \( a = 3\omega_0 \) and \( a = 6\omega_0 \), respectively. Other parameters are the same as Fig. 5. Right Panel: the solid red (dashed blue) lines in Left Panel is shifted upward (downward) to better distinguish the three cases.

To obtain a deeper understanding of how the system-bath coupling suppresses the non-Markovianity in the strong coupling regime, we plot the time evolution of the trace distances for three values of \( a \) in Fig. 6. The red solid line, the black dashed dotted line and the blue dashed line represent the trace distances with \( a = 2\omega_0 \), \( a = 3\omega_0 \) and \( a = 6\omega_0 \), respectively. Other parameters are the same as those in Fig. 5. The black and blue lines are shifted downward in the right panel to better distinguish the curves. It is found that the increase of coupling strength will not affect the decay rate of the trace distance, but does affect its oscillation amplitudes. This is because in this coupling regime, the behavior of the sys-
would focus on extending the discussion to treat multi-chromophore systems. Present work on a single chromophore can be easily extended to treat multi-chromophore systems.

The oscillation of the off-diagonal element of the density matrix. Two specific initial states, labeled by 1 and 2, are considered: \(\rho_{11,1} = 0.5\), \(\rho_{12,1} = 0.2\) and \(\rho_{21,1} = 0.7\), \(\rho_{22,1} = 0.4\). The solid (dashed) blue and red lines represent \(|\rho_{1,12}|^2\) (\(|\rho_{2,12}|^2\)) for \(a = 2\omega_0\) and \(a = 4\omega_0\), respectively. Other parameters are the same as in Fig. 5.

To show this, we plot as a function of time the square of the off-diagonal element of the density matrix. Two initial states, labeled by 1 and 2, are considered: \(|\rho_{1,12}|^2\) (\(|\rho_{2,12}|^2\)) for \(a = 2\omega_0\) and \(a = 4\omega_0\), respectively. Other parameters are the same as in Fig. 5. It is shown in Fig. 7 that the oscillation of the off-diagonal elements decreases with increasing \(a\), but the decay rate stays constant. As \(a\) increases, the oscillation attenuation happens to all states but the ground state.

The oscillation attenuation is hard to obtain because of the complex expectation. In general, this irrelevant contribution is hard to obtain because of the complex structure of the Schrödinger equation, i.e.,

\[
\langle A \rangle^{\text{irrel}} = \text{Tr}_{cq}[A\rho_{cq}(0)] - \text{Tr}_{cq}[\tilde{\rho}_{cq}(0)\text{Tr}_1 (e^{U A e^{-U} \rho_{bath}})],
\]

while the approximation can also be made in the interaction picture.

\[
\langle A \rangle^{\text{I}} = \text{Tr}_{cq} \left( e^{i(H_0 + H_b)t} e^{U A e^{-U} e^{-i(t_0 + H_b)t} Q \tilde{\rho}_{bath,t}(0)} \right),
\]

where \(\tilde{\rho}_{bath,t}(0)\) is the density matrix of the total ensemble in the interaction picture. When \([A,U] = 0\), the irrelevant part vanishes, then the two approximations are actually the same.

Since the density matrix in the original basis is our main concern, we calculate the difference of the expectations \(\langle \sigma_{1} \rangle\) and \(\langle \sigma_{i} \rangle\) for \(i = x, y\) by performing these two approximations. Through some straightforward calculation, it can be found that the relevant part \(\langle \sigma_{1} \rangle^{\text{I}} = 2\text{Re} [\chi(t) / \sigma_{1}(t)]\), where the time-dependent function \(\chi(t)\) is defined as \(\chi(t) := \Theta \{ \sum_k \sin [\omega_k t] g_k^2 / \omega_k^2 \} - 1\). Here \(\Theta \{ \} := \text{Real} \{ \}\). As the polaron transformation generator \(U\) has nothing to do with the subspace...

**B. The chromophore-qubit pair**

In this subsection, we look into the non-Markovian behavior of the chromophore-qubit pair in the presence of the bath. First, its dynamics can be obtained by calculating the vectors \(r_{c}, r_{q}\) and \(m\) in Eq. (27). The expression of \(r_{c}\) has been given in the previous subsection. Now we will focus on \(r_{q}\) and \(m\). Based on Eq. (27), one can easily find that

\[
r_{q} = (\langle \sigma_{x} \rangle, \langle \sigma_{y} \rangle, \langle \sigma_{z} \rangle)^{T},
\]

\[
m = (\langle \sigma_{x} \otimes \sigma_{x} \rangle, \langle \sigma_{y} \otimes \sigma_{y} \rangle, \langle \sigma_{z} \otimes \sigma_{z} \rangle)^{T}.
\]

As some of the operators above do not commute with the generator \(U\), the corresponding irrelevant parts of the expectations do not vanish. In general, this irrelevant contribution is hard to obtain because of the complex structure of the Schrödinger picture, i.e.,

\[
\langle A \rangle^{\text{S}} = \text{Tr}_{cq} [A\rho_{cq}(0)] - \text{Tr}_{cq} [\tilde{\rho}_{cq}(0)\text{Tr}_{1} (e^{U A e^{-U} \rho_{bath}})],
\]

where \(\tilde{\rho}_{bath,t}(0)\) is the density matrix of the total ensemble in the interaction picture. When \([A,U] = 0\), the irrelevant part vanishes, then the two approximations are actually the same.

Since the density matrix in the original basis is our main concern, we calculate the difference of the expectations \(\langle \sigma_{1} \rangle\) and \(\langle \sigma_{i} \rangle\) for \(i = x, y\) by performing these two approximations. Through some straightforward calculation, it can be found that the relevant part \(\langle \sigma_{1} \rangle^{\text{I}} = 2\text{Re} [\chi(t) / \sigma_{1}(t)]\), where the time-dependent function \(\chi(t)\) is defined as \(\chi(t) := \Theta \{ \sum_k \sin [\omega_k t] g_k^2 / \omega_k^2 \} - 1\). Here \(\Theta \{ \} := \text{Real} \{ \}\). As the polaron transformation generator \(U\) has nothing to do with the subspace...
of the chromophore, one arrives at $\langle \sigma_x \otimes \sigma_x \rangle^\text{irrel} = 2\Re e^{iH_0t}\langle \sigma_x \otimes \sigma_x \rangle(t)\rho_{\text{in}}(0)$, where $\{\sigma_x \otimes \sigma_x \}(t) := e^{iH_0t}\langle \sigma_x \otimes \sigma_x \rangle e^{-iH_0t}$ is the time dependent operator of $\sigma_x \otimes \sigma_x$ in the interaction picture. It is therefore found that $\langle \sigma_y \otimes \sigma_y \rangle^\text{irrel} = 2\Re m(t)\langle \sigma_y \otimes \sigma_y \rangle(t)\rho_{\text{in}}(0)$. Utilizing the approximation in the Schrödinger picture, and considering the initial state (8), the irrelevant parts of the expectations of these four operators all vanish. We will compare below the expectation values from these two approximations.

Denote $\Gamma_i = \langle \sigma_i \rangle^\text{irrel} - \langle \sigma_i \rangle^\text{irrel}$ and $\Gamma_{ii} = \langle \sigma_i \otimes \sigma_i \rangle^\text{irrel} - \langle \sigma_i \otimes \sigma_i \rangle^\text{irrel}$, where $i = x, y$, as differences in operator expectation values between the two approximations. In Fig. 8, $\Gamma_x$ and $\Gamma_y$ are plotted as a function of time, where the parameters are set as $\epsilon = \omega_0, \Delta = 0.8\omega_0, T = 0.5\omega_0$, and $a = 4\omega_0$. The spectral density and the relevant parameters are the same as those in Fig. 2. The initial Bloch vector for the chromophore is taken as $r_{c1} = (1, 0, 0)^T$. The blue solid, black dashed dotted, red dashed and pink dotted lines represent $\Gamma_x, \Gamma_y, \Gamma_{xx}$ and $\Gamma_{yy}$, respectively. It is found that the differences in the expectation values are small and short-lived, disappearing beyond $\omega_0t = 2$. For convenience, the approximation performed in the Schrödinger picture is chosen because the irrelevant part of the expectation values we are interested in always vanish in this case.

Thus, for the zeroth order approximation, taking into account the initial state Eq. (8), the expectation value of operator $A$ has the form

$$\langle A \rangle = \text{Tr}_{\text{q}} \left[ \tilde{\rho}_{\text{q}}(t) \text{Tr}_{\text{b}} \left( e^{U \rho_{\text{b}}} A e^{-U} \rho_{\text{b}} \right) \right].$$

(36)

Here $A = \sigma_{x1}, \sigma_{y1}, \sigma_x \otimes \sigma_x$, or $\sigma_y \otimes \sigma_y$. Density matrix dynamics can be obtained for the chromophore-qubit pair in the original basis. Keeping in mind the fact that $e^{U \sigma_{x1} e^{-U}} = \sigma_{x1} \cosh B + i \sigma_{y1} \sinh B$, and $\langle \sinh B \rangle = 0$, and utilizing the zeroth approximation, the expectation value of $\sigma_{x1}$ in the original basis can be written as $\langle \sigma_{x1} \rangle = \Theta \text{Tr}_{\text{q}} \left[ \sigma_{x1} \tilde{\rho}_{\text{q}}(t) \right]$. Similarly, one can obtain that $\langle \sigma_{y1} \rangle = \Theta \text{Tr}_{\text{q}} \left[ \sigma_{y1} \tilde{\rho}_{\text{q}}(t) \right]$ and $\langle \sigma_x \otimes \sigma_x \rangle = \Theta \text{Tr}_{\text{q}} \left[ \sigma_x \otimes \sigma_x \tilde{\rho}_{\text{q}}(t) \right]$ for $i = x, y$. Moreover, based on Eq. (26), we have $\langle \sigma_{x1} \rangle = \text{Tr}_{\text{q}} \left[ \sigma_{x1} \tilde{\rho}_{\text{q}}(t) \right]$ and $\langle \sigma_x \otimes \sigma_x \rangle = \text{Tr}_{\text{q}} \left[ \sigma_x \otimes \sigma_x \tilde{\rho}_{\text{q}}(t) \right]$. Finally, one can obtain the density matrix of the chromophore-qubit pair in the original basis under the zeroth order approximation as

$$\rho_{\text{q}}(t) = M_{\Theta} \circ \tilde{\rho}_{\text{q}}(t),$$

(37)

where $\circ$ denotes the Hadamard product and

$$M_{\Theta} = \begin{pmatrix}
\Theta & 1 & 1 & \Theta \\
1 & \Theta & 1 & \Theta \\
\Theta & 1 & \Theta & 1 \\
The solid line represents the trace distance before the polaron transformation and the blue dashed line represents that after the transformation. The trace distances of the density matrices for the chromophore-qubit pair and the quasi-particle. The parameters in this plot are set as $\epsilon = \omega_0, \Delta = 0.8\omega_0$, and $a = \omega_0$. The initial states of the chromophore-qubit pair are chosen as $|c_0\rangle \otimes |0\rangle_\text{q}$ and $|c_0\rangle \otimes |0\rangle_\text{q}$. Here $\rho_{c,\text{half}}$ reads

$$\rho_{c,\text{half}} = \frac{1}{2} \begin{pmatrix}
1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1
\end{pmatrix}.$$  

(39)

After the polaron transformation, the initial states of the quasi-particle take the same form. In Fig. 9, the solid and dashed lines depict the trace distance of the density matrices before and after the polaron transformation, respectively, and it is clear that before the polaron transformation, there are oscillations in the trace-distance dynamics implying non-Markovian behavior, while after the polaron transformation, the trace distance monotonously decreases with the passage of time, an observation in agreement with the well-known fact that the polaron transformation reduces the effective interaction between the quasi-particle and the bath.

V. CONCLUSION

In conclusion, utilizing a non-Markovian time-convolutionless polaron master equation we probe dynamics of a central chromophore interacting with a phonon reservoir via a probe qubit. An in-depth analysis is carried out on the non-Markovian behavior of the dynamics, for which a measure of non-Markovianity is provided based on dynamical fixed points of the system. This measure of non-Markovianity is analogous to the BLP measure but has a $O(N)$ numerical advantage.

Using this measure, we have discussed the effects of the bath temperature and the strength of the chromophore-qubit coupling on the non-Markovian behavior of the chromophore-qubit pair. The parameters in this plot are set as $\epsilon = \omega_0, \Delta = 0.8\omega_0$, and $a = \omega_0$. The initial states of the chromophore-qubit pair are chosen as $|c_0\rangle \otimes |0\rangle_\text{q}$ and $|c_0\rangle \otimes |0\rangle_\text{q}$. Here $\rho_{c,\text{half}}$ reads

$$\rho_{c,\text{half}} = \frac{1}{2} \begin{pmatrix}
1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1
\end{pmatrix}.$$  

(39)

After the polaron transformation, the initial states of the quasi-particle take the same form. In Fig. 9, the solid and dashed lines depict the trace distance of the density matrices before and after the polaron transformation, respectively, and it is clear that before the polaron transformation, there are oscillations in the trace-distance dynamics implying non-Markovian behavior, while after the polaron transformation, the trace distance monotonously decreases with the passage of time, an observation in agreement with the well-known fact that the polaron transformation reduces the effective interaction between the quasi-particle and the bath.
chromophore. It is found that an increase in the temperature brings about a reduction in the non-Markovianity. In the weak coupling regime, an increase in the coupling is found to enhance the non-Markovianity, while in the strong coupling regime, it suppresses the non-Markovianity. The non-Markovianity maximum is found in the near resonance regime (around \( \alpha = \omega_0 \)) for \( T = 0.5\omega_0 \), a value that may be sensitive to other system parameters such as the temperature and the spectral density of the bath. In addition, we compare the non-Markovian behavior of the chromophore-qubit combination before and after the polaron transformation. It is found that the non-Markovian behavior vanishes after the polaron transformation. Non-Markovianity is of great interest in a variety of topics, such as steady-state entanglement maintenance [60], quantum teleportation [61], and precision estimation under noise in quantum metrology [62].
