I. INTRODUCTION

Frequency-hopping (FH) signals have been widely used in wireless communications and other information systems due to their inherent capability of low interception and anti-jamming [1]–[6]. In practical civilian and military applications, estimating the parameters of the FH signals is of great importance [2], [7]. In civilian wireless networks [2], [8], for example, estimating FH signals is vital to detect multiple users, avoid collision and achieve robust performance against interference [9]. In military communications, blind estimation is also required to estimate and intercept the intentional interference [10]. The main challenges of FH signal estimation are to robustly estimate the hopping time and frequency with unknown hopping pattern particularly in low signal-to-noise ratio (SNR) environments [2], [11]. Since the maximum likelihood estimation requires a computational intractable combinatorial search [7], [11], many other alternative methods are developed.

Among many approaches that have been reported to cope with the FH spectrum estimation problem, time-frequency representation (TFR) is an intuitive and useful tool to exhibit the frequency contents of non-stationary signals. Spectrogram obtained by short-time Fourier transform (STFT) is a popular choice for estimating FH signals, since it can provide a TF distribution free of cross-terms compared to other distributions in Cohen’s class [12]. However, the spectrogram of the signal inevitably suffers from limited resolution and poor signal energy concentration, which greatly restricts the performance of subsequent processing such as entropy or gradient based refinement [5], [13], [14].

In [15], a maximum likelihood approach is developed for estimating a single FH signal. In this method, the FH signal estimation problem has been formulated in a maximum likelihood framework, where hopping time and frequency are treated as unknown parameters. Empirical results show that the algorithm has achieved desirable performance of estimating hopping time and frequency in relatively high SNR environments. Since the formulation of this algorithm depends on the parametric modeling of a single FH signal, it cannot be straightforwardly extended to multiple FH signals due to the undesirable increase in dimensionality of the parameters and the induced intractable computational complexity [15].

In [7], [16], multiple FH signal estimation is considered in a sparse linear regression (SLR) framework, where a fused least absolute shrinkage and selection operator (LASSO) alike approach is used [17]. In this framework, two penalty terms are incorporated to encourage sparsity and smoothness in the frequency and TF domain, respectively. Since this approach is based on the compressive sensing concept, it can achieve better estimation accuracy in various scenarios. Despite its success in estimating FH signals, the experimental results show that this approach does not scale well under low SNR conditions. Although the bounds of regularization parameters are given in [7] for desirable recovery, parameter tuning process is still required to obtain robust performance of the algorithm, where optimal parameter selection is still an open problem.

Another approach is developed to cope with hopping time and frequency estimation in FH networks particularly for multi-channel systems [2], [18]. An expectation maximization (EM) approach is employed to iteratively estimate the amplitude, hopping time and frequency. In this approach, the success of the EM algorithm depends largely on the proper selection of initial value, where a de-noised STFT is often used to initialize

Robust Frequency-Hopping Spectrum Estimation based on Sparse Bayesian Method

Lifan Zhao, Lu Wang, Guoan Bi, Senior Member, IEEE, Liren Zhang, Senior Member, IEEE, Haijian Zhang, Member, IEEE

Abstract—This paper considers the problem of estimating multiple frequency hopping signals with unknown hopping pattern. By segmenting the received signals into overlapped measurements and leveraging the property that frequency content at each time instant is intrinsically parsimonious, a sparsity-inspired high-resolution time-frequency representation (TFR) is developed to achieve robust estimation. Inspired by the sparse Bayesian learning algorithm, the problem is formulated hierarchically to induce sparsity. In addition to the sparsity, the hopping pattern is exploited via temporal-aware clustering by exerting a dependent Dirichlet process prior over the latent parametric space. The estimation accuracy of the parameters can be greatly improved by this particular information-sharing scheme, and sharp boundary of the hopping time estimation is manifested. Moreover, the proposed algorithm is further extended to multi-channel cases, where task-relation is utilized to obtain robust clustering of the latent parameters for better estimation performance. Since the problem is formulated in a full Bayesian framework, labor-intensive parameter tuning process can be avoided. Another superiority of the approach is that high-resolution instantaneous frequency estimation can be directly obtained without further refinement of the TFR. Results of numerical experiments show that the proposed algorithm can achieve superior performance particularly in low signal-to-noise ratio scenarios compared with other recently reported ones.

Index Terms—Dirichlet process, multiple frequency-hopping signals, sparse Bayesian learning, stick-breaking process, time-frequency representation.

the algorithm. In low SNR environments, however, it is hard to obtain a desirable initial TFR, which will inevitably result in degraded performance of the EM algorithm.

In order to accurately and robustly estimate multiple FH signals in low SNR environments, a novel enhanced high-resolution TFR is proposed by exploiting sparsity and piecewise smoothness in the TF domain. In this paper, we develop a linear and high-resolution TFR based on the sparse Bayesian framework, encouraging sparsity in spectral and smoothness in TF domain simultaneously. More concretely, rather than reconstructing the sparse spectrum at each time instant independently to achieve high resolution [19], the proposed formulation can also exploit the piecewise smoothness in the TF domain by utilizing the dependent Dirichlet process (dDP) for the latent parameter modeling. The proposed framework can be considered as a multi-task learning problem with unknown task relations. The main idea is to exploit the frequency hopping patterns in a statistical manner.

The rest of the paper is organized as follows. In Section II, the frequency-hopping problem is introduced and the sparse signal model is formulated. In Section III, FH signal estimation problem is formulated in a sparse Bayesian framework. Further discussions on related work are also presented in this section. Multi-channel extension of the proposed method is presented in Section IV. Numerical experiments and conclusion are given in Section V and Section VI, respectively.

Notation: Vectors and matrices are denoted by bold symbol. For a matrix \( A \), \( A^H \) and \( A^{-1} \) denote the conjugate and inverse of the matrix, respectively. \( \ell_p \) norm of a vector is defined by \( \| x \|_p = \left( \sum_{i=1}^{N} |x_i|^p \right)^{1/p} \). \( N(X|\mu, \Sigma) \) and \( \mathcal{CN}(X|\mu, \Sigma) \) denote multivariate real and complex Gaussian distributions. \( \text{Bern}(x|p) \) denotes Bernoulli distribution and \( \Gamma(x|a, b) \) denotes Gamma distribution.

II. PRELIMINARIES AND PROBLEM FORMULATION

A. Signal Model

Let us consider a noise corrupted and interference free FH signal,

\[
y(t) = \sum_{k=1}^{K_i} \sigma_{i,k} e^{j2\pi f_i t + \nu(t)}, \quad t_{i-1} < t < t_i
\]

where \( K_i \) is the number of hopping frequencies during the \( i \)-th system dwell time, \( \sigma_{i,k} \) is the amplitude of the signal associated with the \( i \)-th system dwell time and \( k \)-th hopping frequency. The noise vector is denoted by \( \nu(t) \), which is an independent identical distributed (i.i.d.) Gaussian random variable. The discrete form of \( y(t) \) is expressed as

\[
y(n) = \sum_{k=1}^{K_i} \sigma_{i,k} e^{j2\pi f_i n/f_s} + \nu(n/f_s), \quad n_{i-1} < n < n_i
\]

where \( f_s \) is the sampling frequency larger than the Nyquist sampling frequency, i.e., \( f_s > 2 \cdot \max \{ f_{i,j} : i = 1, \ldots, N_d \} \) and \( j = 1, \ldots, K_i \), and \( N_d \) is the number of system-wise dwells. In practical systems, the number of signals \( K_i \), the system dwell time \( n_i \) and hopping frequency \( f_{i,k} \) are all unknown to the user and are required to be estimated.

B. The Sparsity Based Estimator via SLR

The frequency hopping signal estimation problem can be formulated within a sparse framework by exploiting the sparsity and spectral smoothness [7]. It can be formulated as the following convex optimization problem

\[
\hat{x} = \arg \min_x \left[ \frac{1}{2} \| y - Wx \|_2^2 + \lambda_1 \| x \|_1 + \lambda_2 \| Dx \|_1 \right]
\]

where the first term is for data fitting, the second and third terms are for encouraging sparsity in frequency and differential-time domain, respectively [7]. The \( \lambda_1 \) and \( \lambda_2 \) are used as regularization parameters.

It has been shown that sparsity-induced approach can achieve state-of-the-art performance over many other methods. However, an important shortcoming of the SLR based approach is that it does not provide robust estimation performance in low SNR environments, due to the sensitivity of the differential operator \( \| Dx \|_1 \) used in fused LASSO [17]. Furthermore, the convex optimization based approach requires appropriate tuning of parameters, where optimum solution is still an open problem.

C. Proposed Sparse Bayesian Model

In order to alleviate the drawbacks, a new approach is proposed to make use of the TF processing scheme by segmenting the received signals into overlapped segments, meanwhile exploiting sparsity and smoothness in time and TF domain, respectively. Let us assume a uniformly dense grid \( \{ f_1 : \Delta f : f_N \} \) including all the hopping frequencies, where \( \Delta f \) is the frequency interval and \( N \) is the number of frequency bins. Similar to the spectrogram based method, the signal is segmented into \( M \) over-lapped measurements, where \( P \) is the window length for the segmentation, as shown in Fig. 1. The length of the segment is often chosen to be appropriate for stable sparse recovery [20] as well as low bias in hopping transition time estimation [12], which will be formally defined in Section III-C. Then, (2) becomes

\[
Y = [y_1, y_2, \ldots, y_M] = \Phi [x_1, x_2, \ldots, x_M] + \nu
\]

where \( y_i \in \mathbb{C}^{P \times 1} \) denotes the \( i \)-th segment of the received signal, \( x_i \in \mathbb{C}^{N \times 1} \) represents the spectrum of the \( i \)-th segment to be estimated and \( \nu \in \mathbb{C}^{P \times N} \) represents the unknown noise. The matrix \( \Phi = [\Phi(f_1), \ldots, \Phi(f_N)] \in \mathbb{C}^{P \times N} \) is constructed as
a partial Fourier matrix (i.e., \( P < N \)), where each atom \( \Phi(f_i) \) is \([e^{-2\pi i f_i 1}, \ldots, e^{-2\pi i f_i P/f_i}]^T\). The likelihood function for the signal model can be therefore expressed as,

\[
p(y_i|x_i, \alpha_0) = \mathcal{N}(\Phi x_i, \alpha_0^{-1} \mathbf{I}), \quad i = 1, \ldots, M. \tag{5}
\]

where \( \alpha_0 \) is the noise precision parameter, i.e., the reciprocal of variance.

Remark 1: Since the proposed formulation in (4) is a grid based method, it can potentially allow non-uniform or sub-Nyquist sampling by manipulating matrix \( \Phi \), which is similar to the SLR method proposed in [7]. In realistic application, this formulation will be feasible to deal with signals containing high frequency components based on compressive sensing concept.

III. PROPOSED FH ESTIMATION ALGORITHM

In this section, the FH signal estimation problem is formulated within a sparse Bayesian framework that encourages both sparsity and smoothness in TF domain. In particular, the latent parameters are encouraged to cluster in temporal aware manner. Subsequent parameter estimation are carried out based on computational efficient variational Bayesian inference technique.

A. Multi-task Learning via Logistic Stick-Breaking Process

In our problem, the signal exhibits temporal correlation after the segmentation manipulation. In other words, it is natural that proximal measurements are more likely to share the same latent parameter. Therefore, rather than explicitly employing Dirichlet process (DP) based Bayesian compressive sensing [21], [22], we propose to incorporate temporal smoothness in TF domain by utilizing the dependent Dirichlet process (dDP) during sparse recovery process. In this way, the clustering accuracy of the latent parameter will be improved, which in turn will enhance the subsequent estimation of the sparse signal.

In sparse Bayesian modeling, each of the \( x_i \) is hierarchically modeled to induce sparsity. To further exploit the property that the FH signals exhibit piecewise smoothness in the TF domain, we impose this property by encouraging the variance parameters \( \alpha \) to cluster in a temporal aware and statistical manner. To encourage the latent parameter to cluster in a temporal aware manner, a logistic stick-breaking process [21] is employed. The graphic model can therefore be represented in Fig. 2. With this graphic model, let us illustrate the probabilistic model of each node in Fig. 2.

Firstly, a set of independent latent parameters \( \alpha_k \), are defined to allow partially sharing of the variance parameter, where the construction can be given as \(^1\),

\[
p(x_i|\alpha_k, \xi_{ik}) = \prod_{k=1}^K \mathcal{C}N(x_i|0, \alpha_k^{-1}) \xi_{ik} \quad i = 1, \ldots, M. \tag{6}
\]

\(^1\)The number of latent parameters \( K \) should theoretically approach infinity in DP based modeling. However, in order to obtain tractable Bayesian inference of the graphic model, \( K \) is often truncated to a value similar to the number of measurements \( M \) [22].

where \( \xi_{ik} \) is defined as the indicator variable with values of 0 and 1. If \( \xi_{ik} = 1 \), it means the \( i \)-th measurement is generated from Gaussian distribution with variance \( \alpha_k \). More strictly, only one of \( \{\xi_{ik}, k = 1, \ldots, \infty\} \) should be 1.

Secondly, to induce sparsity, the variance of the sparse signal \( \alpha_k \) is modeled as an inverse Gamma distribution,

\[
p(\alpha_k|c, d) = \Gamma(\alpha_k|c, d), \quad k = 1, \ldots, K. \tag{7}
\]

This above-described hierarchical modeling can impose sparsity, since the marginalized distribution obeys a sparsity-inducing multivariate student’s t distribution [23], [24].

Thirdly, apart from sparsity, to encourage the clustering of latent parameter \( \alpha_k \) in a temporal related sense, a dDP is imposed on the latent parameters \( \alpha_k \).

\[
\Gamma(a, b)
\]

where \( \pi_k(t_i) \) represents the probability of assigning \( \alpha_k \) to the \( i \)-th spectrum \( x_i \). The probability of \( \xi_{ik} \) in (9) is specified to be Bernoulli distribution with parameter defined by a logistic function [21],

\[
p(z_{ik}|w_k) = \text{Bern}(z_{ik} | \sigma(w_k^T \psi_i)) \tag{10}
\]

where \( \sigma \) is the sigmoid function [26], and \( \psi_i \) represents the \( i \)-th temporal kernel basis vector and \( w_k \) is the sparse coefficient to be estimated. In the following, the construction of basis \( \Psi_i \) and coefficient \( w_k \) will be described. A commonly used Gaussian kernel [26] is utilized to define \( \psi_i \) in (10),

\[
\psi_i = \begin{bmatrix} \exp\left(-\frac{(t_i - s_1)^2}{\gamma_i}\right) & \cdots & \exp\left(-\frac{(t_i - s_g)^2}{\gamma_i}\right) \end{bmatrix}^T \tag{11}
\]

where \( t_i \) is the discrete time of the signal and \( s_1 : s_g, g < M \), is the sampled time set (uniformly under-sampled from the
time index). As observed from the above-described model, the mixing coefficient is temporally related.

In addition, the weight coefficient \( w_k \) in (10) is further modeled as Gaussian-Gamma distribution to encourage sparsity [23].

\[
p(w_k | \lambda_k) = \mathcal{N}(w_k | 0, \lambda_k) \\
p(\lambda_k | e, f) = \prod_{i=1}^M \Gamma(\lambda_{ki} | e, f).
\] (13)

This hierarchical modeling will induce \( w_k \) to be a sparse vector [23], [24]. The induction of sparsity for \( w_k \) is to achieve smooth segmentation since the dominant entry in each \( w_k \) can produce a smooth segment as indicated in [21] and our experimental results. The intuition of this particular modeling on mixing weight \( \pi_k(t_i) \) in (8) is to make the clustering procedure be temporal dependent, where time-frequency smoothness of the FH signals can be well exploited.

Finally, the noise precision parameter \( \alpha_0 \) is modeled to follow a Gamma distribution for convenient inference,

\[
p(\alpha_0 | a, b) = \Gamma(a, b) \tag{14}
\]

where convenient inference of the noise precision parameter \( \alpha_0 \) can be enabled for modeling conjugacy [20].

The above-described model can encourage sparsity of the spectra by hierarchical sparse modeling and temporal aware clustering, respectively. Combining the likelihood function in (5) with the above-described hierarchical priors, the joint probability can be expressed by

\[
p(y, x, z, w, \lambda, \alpha_0) = \prod_{i=1}^M \prod_{k=1}^K p(y_i | x_i, \alpha_0) \cdot [p(x_i | \alpha_{ik})]^{z_{ik}} \\
\cdot p(\alpha_j | e, d) \cdot p(z_{ik} | w_k) \cdot p(w_k | \lambda_k) \\
\cdot p(\lambda_k | e, f) \cdot p(\alpha_0 | a, b). \tag{15}
\]

Therefore, the estimation of these parameters can be obtained by calculating the following posterior,

\[
p(x, \alpha, z, w, \lambda, \alpha_0 | y) = p(x, \alpha, z, w, \lambda, \alpha_0 | y) / p(y). \tag{16}
\]

The calculation of marginal distribution \( p(y) \), however, demands the computationally intractable multi-dimensional integral. Since the closed-form solution of the posterior is generally not accessible, approximated or sampling approach is required for Bayesian inference [26].

**Remark 2**: In FH signals estimation, the latent parameter \( \alpha \) cannot be explicitly assumed to be fully independent or dependent in sparse Bayesian learning (SBL) or block SBL (BSBL). In SBL [20], [23], [24], [27], [28], the sparse signals \( x_i, i = 1, \ldots, M \), are hierarchically modeled to impose sparsity. The prior of \( x_i \) is modeled as a complex Gaussian distribution with independent variance vector \( \alpha_i \), \( p(x_i | \alpha_i) = \mathcal{CN}(0, \alpha_i^{-1}) \), \( i = 1, \ldots, M \). In contrast, the block SBL (BSBL) approach [29] uses a shared \( \alpha \) defined by exploiting the support-sharing property of the measurements. The prior of \( x_i \) is modeled as, \( p(x_i | \alpha) = \mathcal{CN}(0, \alpha^{-1}) \) for \( i = 1, \ldots, M \).

**Remark 3**: Rather than imposing the sparsity in frequency domain and hop point explicitly as in SLR approach, the proposed model implicitly exploits the temporal clustering property of the linear time frequency distribution along with sparsity. In this manner, the sensitivity of differential operator can be relaxed by the proposed multi-task learning framework [21], [30]. It is seen that the sparsity helps to recover high-resolution TF distribution and the temporal clustering property enhances the recovery of TF distribution. Our empirical results have validated the robustness of the proposed method.

### B. The Bayesian Inference

Since direct inference of the graphic model is generally intractable, a straightforward approach is to sample the distribution by standard Markov Chain Monte Carlo (MCMC) approach. However, the MCMC approach suffers from high computational complexity in high dimensional scenarios and its general convergence is difficult to diagnose. Instead, we use a computationally efficient approximation procedure known as variational Bayesian inference (VBI) to obtain efficient inference and the guaranteed convergence. With the mean-field assumption, the factorized posterior can be approximated via the following expression,

\[
p(x, \alpha, z, w, \lambda, \alpha_0 | y) \approx q(x)q(\alpha)q(z)q(w)q(\lambda)q(\alpha_0) \tag{17}
\]

where the parameter is defined as \( \Theta = \{ x_i, \alpha_k, z_{ik}, w_k, \lambda_k, \alpha_0 \} \). With this assumption, let us derive the optimal approximation to minimize the Kullback Leibler (KL) divergence between the approximated distribution and true posterior,

\[
q^*(\Theta) = \arg \min_{\Theta} \int q(\Theta) \log \frac{p(\Theta | y)}{q(\Theta)} d\Theta. \tag{18}
\]

In summary, the optimal distribution for each \( \Theta_k \) can be expressed as,

\[
q^*(\Theta_k) \propto \exp \left[ \mathbb{E}_{i \neq k} [\ln p(Y, \Theta_k)] \right]. \tag{19}
\]

Since the graphic model is formulated hierarchically based on the conjugacy of the distributions, we can conveniently derive the following updating formula for the individual parameter based on the mean value of their approximated posterior distribution. The derivations of updating rules for each of the parameters are given as follows.

1) **Updating rule of noise precision parameter \( \alpha_0 \)**: According to the Markov blanket of \( \alpha_0 \) in the graphic model, the optimal approximated distribution \( q(\alpha_0) \) should obey.

\[
q(\alpha_0) \propto \prod_{i=1}^M p(y_i | \Phi x_i; \alpha_0) p(\alpha_0 | a, b). \tag{20}
\]

Since the conjugacy of Gaussian likelihood \( \prod_{i=1}^M p(y_i | \Phi x_i; \alpha_0) \) and Gamma prior \( p(\alpha_0 | a, b) \) will result in a Gamma posterior, the update equation for the noise precision parameter \( \alpha_0 \) can be derived by substituting (5) and (14) into (20),

\[
\ln q(\alpha_0) \propto - \alpha_0 \sum_{i=1}^M \| y_i - Ax_i \|^2 + n M \ln \alpha_0 \\
+ (a - 1) \ln \alpha_0 - b \alpha_0. \tag{21}
\]
Therefore, the approximated posterior for \( \alpha_0 \) obeys a Gamma distribution with parameters \( \hat{a} \) and \( \hat{b} \) expressed as,

\[
\hat{a} = M \cdot n + a \tag{22}
\]

\[
\hat{b} = - \sum_{i=1}^{M} \left[ ||y_i - \Phi \mu_i||^2_2 + \text{trace}(\Phi \Sigma_i \Phi^H) \right]. \tag{23}
\]

Since only the first order momentum of the parameter is utilized in the updating rules for other parameters, the mean of \( \alpha_0 \) is given accordingly as \( \mathbb{E}[\alpha_0] = \hat{a}/\hat{b} \).

2) Updating rule for sparse coefficient \( x_i \): According to the Markov blanket of the \( x_i \) in the graphic model, the optimal approximated distribution \( q(x_i) \) should also obey,

\[
q(x_i) \propto \prod_{j=1}^{K} [p(y_i|x_j)p(x_i|\alpha_j)]^{\xi_{ij}}. \tag{24}
\]

Due to the conjugacy of Gaussian distribution, the optimal distribution for \( x_i, i = 1, \ldots, M \), is given by substituting (5) and (6) into (24),

\[
\ln q(x_i) \propto -\alpha_0 \cdot ||y_i - \Phi x_i||^2_2 + \sum_{k=1}^{K} -\xi_{ik} x_i^H \alpha_k x_i
\]

\[
\propto -x_i^H \left( \sum_{k=1}^{K} \xi_{ik} \alpha_k + \alpha_0 \Phi^H \Phi \right) x_i
\]

\[+ x_i^H \Phi^H y_i + y_i^H \Phi x_i. \tag{25}\]

Based on the above equation, the mean and covariance matrix of the approximated posterior distribution can be given as,

\[
\mu_i = \alpha_0 \Sigma_i^{-1} \Phi^H y_i \tag{26}
\]

\[
\Sigma_i = \left[ \text{diag} \left( \sum_{k=1}^{K} (\xi_{ik}) \cdot \alpha_k \right) + \alpha_0 \Phi^H \Phi \right]. \tag{27}\]

It is seen that the calculation of (26) requires the inversion of matrix \( \Sigma_i \). To reduce the computational complexity of the matrix inversion of \( \Sigma_i^{-1} \), the equation for \( \Sigma_i^{-1} \) can be expanded by matrix inverse lemma [20],

\[
\Sigma_i^{-1} = \text{diag} \left( \sum_{k=1}^{K} (\xi_{ik}) \cdot \alpha_k \right)^{-1} - \text{diag} \left[ \sum_{k=1}^{K} (\xi_{ik}) \cdot \alpha_k \right]^{-1} \Phi^H \]

\[\cdot C^{-1} \Phi \text{diag} \left[ \sum_{k=1}^{K} (\xi_{ik}) \cdot \alpha_k \right]^{-1} \tag{28}\]

where the matrix \( C \) is further expressed as,

\[
C = \alpha_0^{-1} I + \Phi \text{diag} \left[ \sum_{k=1}^{K} (\xi_{ik}) \cdot \alpha_k \right]^{-1} \Phi^H. \tag{29}\]

It can be observed from the above equations that the updating rule for \( \mu_i \) will incorporate all the latent parameter \( \alpha_k, k = 1: K \), and the corresponding indicator variables \( \xi_{ik} \). It is noted that when \( \xi_{ik} = 1 \), the \( i \)-th sparse coefficient will only be influenced by the support of latent parameter \( \alpha_k \). More concretely, the sparse coefficient with \( \xi_{ik} = 1, i = 1: M \), will be influenced by the clustering of the latent parameter \( \alpha_k \).

3) Updating rule for the precision vector of the sparse coefficient \( \alpha \): Based on the Markov blanket of the \( \alpha \) in Fig. 2, the optimal approximated distribution \( q(\alpha_k) \) should obey,

\[
q(\alpha_k) \propto \prod_{i=1}^{M} [p(x_i|\alpha_k)]^{\xi_{ik}} p(\alpha_k|c, d). \tag{30}\]

Substituting (6) and (10) into (30), we have,

\[
\ln q(\alpha_k) \propto -\alpha_0 \cdot \sum_{i=1}^{M} \xi_{ik} [-x_i^H \alpha_k x_i + \sum_{j=1}^{N} \ln \alpha_{kj}] + (c - 1) \ln \alpha_k - d \alpha_k. \tag{31}\]

Based on the above equation, the mean and covariance matrices of the approximated posterior distribution are given as,

\[
\hat{c}_{kj} = c + \sum_{i=1}^{M} \langle \xi_{ik} \rangle \tag{32}
\]

\[
\hat{d}_{kj} = d + \sum_{i=1}^{M} \langle \xi_{ik} \rangle \cdot [w^2_{ij} + \Sigma_i (j, j)]. \tag{33}\]

Similar to the updating rule for \( x_i \), who utilizes all the latent parameters \( \alpha_k \), estimation of each \( \alpha_k \) also incorporates all the estimation of sparse coefficient \( x_i \) and the corresponding indicator parameters \( \xi_{ik} \).

4) Updating rule for the indicator variable \( z_{ik} \): Because the posterior of \( z_{ik} \) is only dependent on \( x_i \), we can obtain

\[
q(z_{ik}) \propto \prod_{j=k}^{K} [p(x_j|\alpha_j)]^{\xi_{ij}} p(z_{ik}|\sigma(g_k(t_i))] \tag{34}\]

where \( \mathbf{w}_T \psi_i \) is defined as \( g_k(t_i) \) for notational brevity. Substituting (6) and (10) into (34), the approximated posterior is given in (35) in next page. Since the prior of \( z_{ik} \) is not conjugate to its likelihood, the derivation of the posterior is given in the following proposition.

**Proposition 1:** The probability of \( p(z_{ik}) = 1 \) and \( p(z_{ik}) = 0 \) are given by (55) and (56) in Appendix A, respectively.

**Proof:** The proof is given in Appendix B.

It is observed from the derivation that the updating rule for \( z_{ik} \) involves both the sparse signals and their corresponding latent parameters.

5) Updating rule for the weight coefficient \( w_k \): Based on the Markov blanket of \( w_k \) in Fig. 2, the optimal approximated distribution \( q(w_k) \) should obey,

\[
q(w_k) \propto p(w_k|\lambda_k^{-1}) \prod_{i=1}^{M} [p[g_k(t_i)]]. \tag{36}\]

In general, the inference is intractable due to the complexity in the logistic function, where we seek a
\[
\ln q(z_{ik}) \propto \sum_{j=k+1}^{K} z_{ik}[\xi]\sum_{n=1}^{N} \ln \alpha_{jn} - \mathbf{x}_j^H \text{diag}(\alpha_j) \mathbf{x}_i + z_{ik} \ln \sigma(g_k(t_i)) + (1 - z_{ik})[-w_k^T \psi_i + \ln \sigma(g_k(t_i))] \tag{35}
\]

variational bound for logistic function approximation.

**Proposition 2:** Based on the quadratic variational bound of the logistic function\(^2\), the approximated posterior of \(w_k\) obeys a Gaussian distribution with mean and covariance matrices given by,

\[
\hat{w}_k = \Sigma_{w_k} \cdot \sum_{i=1}^{M} [\hat{z}_{ik} - 0.5] \cdot \psi_i \tag{37}
\]

\[
\Sigma_{w_k} = [\lambda_k \mathbf{1} + \sum_{i=1}^{2} \cdot \psi_i \psi_i^H f(\eta_{ik})]^{-1}. \tag{38}
\]

**Proof:** The proof is given in Appendix C. \(\blacksquare\)

6) **Updating rule for \(\lambda_k\):** Based on the Markov blanket of \(\lambda_k\) in Fig. 2, the optimal approximated distribution \(q(\lambda_k)\) should obey,

\[
q(\lambda_k) \propto p(w_k|\lambda_k^{-1})p(\lambda_k|e, f). \tag{39}
\]

Similarly, the parameter \(\lambda_k\) obeys a Gamma distribution,

\[
\ln q(\lambda_k) \propto -\frac{1}{2} w_k^T \lambda_k w_k + \frac{1}{2} \ln |\lambda_k| + \sum_{i=1}^{M}[(e - 1) \cdot \ln \lambda_{ki} - f \cdot \lambda_{ki}]. \tag{40}
\]

The approximated posterior for \(q(\lambda_k)\) obeys a Gamma distribution with parameter \(\lambda\) and \(T\) given as,

\[
\hat{\lambda}_k = \left(\frac{1}{2} + e\right) \cdot 1_g \tag{41}
\]

\[
\hat{\lambda}_k = \frac{1}{2} \cdot \text{diag}(\Sigma_{w_k} + w_k w_k^T) + f \tag{42}
\]

where \(1_g\) is a \(g\)-dimensional vector composed of 1.

In summary, the proposed algorithm works in a round-robin manner to iteratively update these parameters, which is given in Algorithm 1. Remarkably, the convergence of the algorithm is guaranteed within this full variational Bayesian framework [31].

**C. Analysis and Discussion**

Sharing information among related tasks will benefit the estimation. However, sharing information among unrelated tasks will induce undesirable bias, which is known as negative transfer in machine learning literature [32]. In this paper, the idea is to encourage the segmented measurements to cluster in the latent parameter space and to sufficiently separate unrelated tasks.

It is noted that the proposed approach is a biased one by introducing hierarchical sparse modeling and logistic stick breaking process into a multi-task compressive sensing framework. However, this bias can encourage to obtain smooth frequency profile in the time-frequency domain as well as accurate hopping pattern estimation.

The intuitive idea of the proposed approach is to utilize sparse signal recovery technique to obtain high resolution time frequency estimation, where temporal aware latent space clustering is imposed to obtain enhanced signal recovery.

**Definition 1:** Without loss of generality, let us consider a signal segment that has one frequency hop between two active frequencies. Let us denote the hopping time index and window length by \(T\) and \(P\), respectively. The hopping transition time index \(J\) with respect to window length \(P\) is then defined as,

\[
J = \{I : I \in T - (P - 1)/2 : T + (P - 1)/2\}. \tag{43}
\]

**Theorem 1:** In noiseless case, i.e., \(V = 0\) in (3), under the assumption that \(\alpha_k\) and the corresponding indicator function \(\xi_{ik}\) are correctly estimated, the algorithm is guaranteed to give correct time-frequency representation of the measurements \(x_i\) during hopping transition time.

**Proof:** The proof is given in Appendix D. \(\blacksquare\)

**D. Computational Complexity**

The STFT requires the least computational complexity to achieve representation performance that should be further improved. The computational complexity of the recently reported SLR method implemented by alternating direction method of multiplier (ADMoM) is in the order of \(O(M^2N^2)\) for one iteration. The computational complexity of the proposed algorithm mainly depends on the matrix inverse operation in

---

\(^2\)The variational bound of logistic function is given as \(\sigma(x) \geq \sigma(\eta) \expv{0.5(x - \eta) - f(\eta)(x^2 - \eta^2)}\), where \(\eta\) is the variational parameter and \(f(\eta)\) is defined as \(\tanh(\eta/2)/(4\eta)\) [26].
calculating (28) and (38). Therefore, it is in the order of $O(M^3 + Kp^3)$ for one iteration. In general, $P$ is chosen to be a small value compared to $M$ and $g$ is also chosen to be smaller than $M$. It is seen that the computational complexities of the proposed algorithm and SLR are in a similar order.

IV. MULTI-CHANNEL FH ESTIMATION

In practical information systems, such as FH wireless network, multiple channel systems are often deployed in order to obtain robust performance against frequency collision and interference [2], [8]. In the estimation process, the direction-of-arrival (DOA), hopping time and frequency are all required to be estimated. In this section, we extend the previously proposed algorithm to multi-channel scenarios.

Assuming $K_s$ sources are impinging on a uniform linear array (ULA) with $L$ sensors, the obtained measurement for each snapshot can be given as

$$y(n) = As(n) + v(n), n = 1, \ldots, N_s \quad (44)$$

where $y(n) \in \mathbb{C}^{L \times 1}$, $A = [a(\theta_1), \ldots, a(\theta_{N_s})] \in \mathbb{C}^{L \times N_0}$, $s(n) \in \mathbb{C}^{N_0 \times 1}$ contains the FH signals, $N_s$ is the number of snapshots. The noise $v(n)$ is assumed to be spatially and temporally uncorrelated,

$$\mathbb{E}[v(n_1)v^H(n_2)] = \alpha_0^{-1} I \cdot \delta_{n_1,n_2}. \quad (45)$$

To estimate the DOA from a sparsity perspective, matrix $A \triangleq [a(\theta_1), a(\theta_2), \ldots, a(\theta_{N_s})] \in \mathbb{C}^{L \times N_0}$ is an over-complete dictionary, whose $i$-th atom

$$a(\theta_i) = [e^{j\pi \cos \theta_i}, e^{j2\pi \cos \theta_i}, \ldots, e^{jL \pi \cos \theta_i}]^H \quad (46)$$
corresponds to an ideal steering vector from spatial angle $\theta_i$.

An integrated model can be formulated by iteratively estimating the DOA and hopping frequencies via a variational sparse Bayesian framework. Rather than the complicated integrated framework, a simple scheme is proposed in this paper to carry out the DOA estimation and FH signal estimation in two separate stages. The intuition behind this scheme is that clustering on the latent parameter space can be more easily carried out with a smaller number of clusters, because the projection manipulation in the DOA estimation stage will simplify the clustering procedure in the FH estimation stage. More concretely, we argue that the proposed approach can particularly benefit from this scheme for the simplification of latent parameter clustering. In Section V, our empirical results show that the proposed scheme can give desirable performances, even in the scenarios that DOA estimation is biased.

In order to efficiently estimate the DOA, $\ell_1$-svd algorithm [33] is utilized by exploiting sparsity in the spatial domain, where other popular sparse regularized approach for DOA estimation can also be used [34], [35]. Empirical results have demonstrated that sparsity-driven algorithms can provide robust estimation of DOA whether the sources are uncorrelated or correlated.

Assuming $N_s$ snapshots are collected and denoting the measurement $Y$ as $[y(1), \ldots, y(N_s)]$, it is obtained

$$Y = a^H(\hat{\theta}_i)Y, \quad i = 1, \ldots, K_s. \quad (47)$$

After the beam-forming manipulation and substituting (44) into (47), we obtain

$$\tilde{Y} = a^H(\hat{\theta}_i)As + V \quad (48)$$

$$= s_i + \sum_{j=1, j \neq i}^{K_s} a^H(\hat{\theta}_j) \cdot a(\theta_j) \cdot s_j + V. \quad (49)$$

It is noted that the projection of signal onto the $i$-th direction can be decomposed as the single FH signal in the $i$-th direction and the projection of other FH signals from other directions into the $i$-th direction. It can be properly assumed that because the term $a^H(\hat{\theta}_i) \cdot a(\theta_j)$ is relatively trivial compared with $s_i$, the second and the third terms in the right hand side of (49) can be treated as noise sources. Therefore, the proposed algorithm for multi-channel frequency hopping signal estimation is summarized in Algorithm 1.
Remark 4: In the multi-channel scenarios, the DOA and hopping frequency estimation are carried out in separate stages, where each hopping signal can be estimated individually. A remarkable advantage of this scheme is that the proposed approach can achieve much better frequency hopping estimation accuracy by the preprocessing that is similar to the beam-forming manipulation, since clustering of the latent parameter can be more accurately carried out for a single frequency hopping signal within this scheme.

Remark 5: This approach can also be flexibly extended to the scenario where different dwells involve different DOAs. In the modification of the algorithm, the DOA estimation is required to be carried out to account for the directional hopping in the spatial domain, which is similar to the frequency hopping estimation in the frequency domain. We do not discuss it further for brevity because the required modification is relatively straightforward.

Algorithm 2 Multi-channel FH signal estimation

1: Input: $y_j, \Phi, \alpha, a, b, c, d, e, f$.
2: 1. DOA Estimation Stage;
3: Use $l_1$-svd algorithm or OMP to estimate DOA [33];
4: 2. FH Signal Estimation Stage
5: for $j = 1 : K_s$ do
6: Beam-forming $\hat{Y}_j = a^H(\hat{\theta}_j)Y$ in (47);
7: Signal Segmentation: $\hat{Y}_j = [\hat{Y}_{j1}, \cdots, \hat{Y}_{jN_s}]$;
8: Use Algorithm 1;
9: end for
10: Output: $X_j, j = 1, \cdots, K_s$.

V. NUMERICAL EXPERIMENTS

In this section, the numerical experimental results are given to evaluate the performance of the proposed algorithm in comparison with other reported ones in both single and multiple channel cases. In the following experiments, the SNR is defined as

$$\text{SNR} = 10\log_{10}\left(\frac{\|s\|^2}{N_s\sigma^2}\right)$$

where $s$ denotes the signal vector, $N_s$ is the number of time indices and $\sigma^2$ is the noise power.

In particular, two performance measures are defined for comparison of hopping time and instantaneous frequency (IF) detection, respectively. The correct hopping time detection ratio is defined as,

$$P_t = \frac{\sum_{i=1}^{M_c} D_t(i)}{M_c}$$

where $M_c$ is the number of Monte Carlo trials and $D_t(i)$ is the number of correct detections in each Monte Carlo trial. The hopping time statistic is defined as $\Delta_n = \|x_{n+1} - x_n\|_2$. A correct hopping time detection is declared if the estimated hopping instant is less than 3 samples away from the associated true hopping instant, which is defined in the same way as in [7].
The incorrect IF detection ratio is further defined as,

\[ E_f = 1 - \left( \sum_{i=1}^{M_c} D_f(i) \right) / M_c \]  

(52)

where \( D_f(i) \) is the correct frequency detection rate in the \( i \)-th Monte Carlo trial.

**A. Single Channel FH Estimation**

In single channel FH estimation, experimental results of the proposed algorithm are qualitatively and quantitatively compared with other recently reported ones in terms of incorrect hopping time detection ratio and incorrect IF detection ratio.

The hopping signals used in the following experiments are generated as follows: the first hopping component is active within the range of time index \([0 : 15]\) and the carrier frequency hops from 13 KHz to 18 KHz within the range of time index \([16 : 63]\). The second hopping component is active within the range of time index \([0 : 31]\) and the carrier frequency hops from 28 KHz to 23 KHz within the range of time index \([32 : 63]\). The third hopping component is active within the range of time index \([0 : 47]\) and the carrier frequency hops from 3 KHz to 6 KHz within the range of time index \([48 : 63]\). The sampling frequency \( f_s \) is 64 KHz.

The regularization parameter is chosen to be \( \lambda_1 = \lambda_1^* / 10 \) and \( \lambda_2 = \lambda_2^* / 20 \) to achieve desirable hopping time and frequency detection in the tested SNRs, where optimal \( \lambda_1^* \) and \( \lambda_2^* \) are given in [7]. The number of Monte Carlo trials is chosen to be 200.

An illustrative example is given in Fig. 3. In this experiment, the segment length of the signal is chosen to be 12 and SNR is 0 dB. It is seen that the spectrogram obtained in Fig. 3 can barely give a clear concentration of the signal, particularly in the first system dwell time. In contrast, all the three sparsity-driven method can give better estimation and concentration due to the utilization of sparsity regularized strategy in the time-frequency domain. Notably, the SLR and Bayesian compressive sensing with Dirichlet prior (BCS-DP) [22] approaches can only detect the second system dwell time while the first dwell time cannot be detected correctly as
shown in Fig. 3(d) and 3(f). The reason for the degraded performance of the SLR is possibly the sensitivity of fused LASSO with heavy noise effects. Meanwhile, since the BCS-DP [32] only operates the clustering procedure for latent parameter without temporal smoothness constraint, the noise might be easily categorized into the existing clusters. The success of the proposed algorithm depends on the temporal aware clustering by utilizing the logistic stick-breaking process, which can encourage spectral smoothness and provide sharp partition simultaneously as indicated from Fig. 3(g) and (h).

In Fig. 4, Monte Carlo experiments are conducted to give quantitative evaluation of the proposed algorithm and the previously reported ones with both two components and three components in terms of hopping time and frequency estimation, respectively. In Fig. 4 (a) and (b), the performance comparison of signal with two components (component 1 and component 2) are given. It can be concluded that with the increase of SNR, SLR and the proposed algorithm can obtain better results than STFT. In particular, the correct hopping time detection ratio of SLR method is even lower than that of STFT particularly when SNR < $-2$ dB. However, our proposed algorithm can achieve the best hopping time and frequency detection ratios. In Fig. 4 (c) and (d), the performance comparison of signal with three components is given. When three components are present, all of the algorithms suffer from degraded performances to a certain extent. However, among all the algorithms, the proposed approach can achieve desirable results compared to the other ones. In summary, it can be observed from these figures that the proposed algorithm can achieve the best hopping time and frequency estimation in low SNR scenarios.

Finally, the performance of the algorithm is compared in terms of the number of reconstructed frequency bins, where the hopping signal used in the experiment is the same as previous ones. The correct hopping time detection ratios obtained by different algorithms are compared, where incorrect IF detection ratios are omitted due to off-grid phenomenon in frequency domain. Figure 5 shows that the proposed algorithm can provide robust performance to achieve the best hopping time detection ratio.

B. Multi-Channel FH Estimation

The performance of algorithm with multi-channel setting is given in this section. We test both two-component and three-component signals. The signal with two components is from DOAs $\theta = [40, 60]$, while the signal with three components is from three DOAs $\theta = [40, 58, 78]$. The hopping patterns are the same as that used in the single channel experiment.

As shown in the illustrative example in Fig. 6, it can be shown that the frequency hopping signal can be separately estimated after beam-forming procedure in (47). Since the
SNR is relatively low in this experiment, the STFT cannot obtain a good signal energy concentration, while the SLR and proposed algorithm give better estimation performance. It is noted that all the three algorithms cannot completely eliminate the influence of the other signal component after beam-forming. This undesirable signal component degrades the hopping time detection based on spectrogram and SLR method as indicated in Fig. 6. It is also observed that both the spectrogram and SLR cannot give the correct hopping time estimation. In contrast, the proposed algorithm can give correct detection for both signal components.

In order to demonstrate the robustness of the proposed algorithm against DOAs estimation bias, a Monte Carlo experiment for frequency hopping signal estimation is carried out in terms of DOA estimation bias. In Fig. 7 (a) and (b), we can observe that the hopping time detection rate decreases with the increase of the DOA bias. The proposed algorithm can give better results than the SLR algorithm in terms of DOA estimation bias. In particular, the proposed algorithm can give more robust results even when the bias is as large as 5 degrees. With the increase in the DOA bias, the SLR algorithm suffers more degradation than that of the proposed algorithm. Moreover, compared with the single channel scenario, the proposed scheme in multi-channel system has superior performance over the SLR based method due to the efficiency of clustering procedures. In particular, the estimation performance of first FH signal is worse than the second one, since component 2 can be more easily estimated and detected with hopping time instant in the center of the signal. It can be concluded that the proposed algorithm gives better performance in multi-channel systems than the previously reported ones, even with a biased DOA estimation.

To validate the proposed multi-channel estimation scheme, the performance comparison is carried out in terms of SNRs, based on frequency hopping signal estimation expectation maximization (FHSE-EM) [18], SLR and the proposed one. In Fig. 8, it can be observed that the proposed method can achieve best performance in both the hopping time detection ratio and incorrect IF detection ratio over other methods. This can validate our argument that the two-stage sparsity-driven scheme is effective for multi-channel FH signal estimation.

VI. CONCLUSION AND FUTURE WORKS

In this paper, we propose a robust frequency hopping signal estimation method based on sparse Bayesian framework. In this approach, we formulate the frequency estimation problem in a multi-task learning manner with signal being partitioned into overlapped measurements. To enhance the estimation accuracy of the sparse spectral coefficients, the latent parameters are encouraged to cluster in a temporal-aware sense by utilizing the logistic stick-breaking process. In this way, more accurate estimation can be obtained due to the use of multi-task learning framework. This novel approach not only avoids the tedious parameter tuning process, but also provides robust performance in low SNR environments.

APPENDIX

A. Review of Dependent Dirichlet Process

Dirichlet process (DP) has been defined to model random measure on measures [25]. This process has been widely used for flexible mixture modeling with an unknown number of mixtures. A DP process can be expressed as,

$$G = \sum_{i=1}^{\infty} \pi_i \delta_{\alpha_i}$$

where $\pi_i$ is the mixing probability for the $i$-th mixture and $\delta_{\alpha_i}$ is point mass located at $\alpha_i$ [25]. Since the explicit formulation of DP from the definition in (53) is not attainable, various constructions of DP have been proposed [36]. In the original DP, exchangeability of the data is often assumed. However, many real data exhibiting correlation does not satisfy this assumption. In order to model the temporal or spatial dependency on the mixture modeling, dependent Dirichlet process [37] is further defined by imposing a stochastic process on mixing weight and base measure,

$$G_x = \sum_{i=1}^{\infty} \pi_i(x) \delta_{\alpha_i(x)}$$

where $\pi_i(x)$ is the dependent mixing weight, $\delta_{\alpha_i(x)}$ is the dependent point mass at $\alpha_i(x)$ and $x$ denotes the temporal or spatial related index. In this way, dependency is imposed on the Dirichlet process.

B. Proof of Proposition 1

When $z_{ik} = 1$, the corresponding indicator parameter $\xi_{ik} = 1$. Consequently, the approximated posterior for $z_{ik} = 1$ is given as

$$q(z_{ik} = 1) \propto \exp \left[ \ln |A_k| - \langle x_i^H A_k x_i \rangle + \ln \sigma(g_k(t_j)) \right].$$

When $z_{ik} = 0$, the corresponding indicator parameters $\xi_{ij} = 0, j < k$. Consequently, the approximated posterior for $z_{ik} = 0$ can be given as

$$q(z_{ik} = 0) \propto \exp \left\{ \sum_{j=k+1}^{K} \left[ \xi_{ij} \ln |A_j| - \langle x_i^H A_j x_i \rangle \right] - w_k^T \psi_i + \ln \sigma(g_k(t_j)) \right\}.$$ 

The resulted approximated posterior can be therefore expressed as

$$q(z_{ik} = j) = \frac{Z_{ikj}}{Z_{i0k} + Z_{ik1}}, \quad j = 0, 1$$

where $Z_{i0k}$ and $Z_{ik1}$ are the values calculated from the right hand side of (55) and (56).

C. Proof of Proposition 2

In the following, a variational lower bound of logistic function, i.e. Gaussian lower bound, will be applied to obtain tractable inference. According to [26] and variational bound,
the lower bound of the approximated posterior can be obtained by

\[
\ln p(w_k) \propto -\frac{1}{2} w_k^T \text{diag}(\lambda_k) w_k + \sum_{i=1}^{M} \log [\sigma(g_k(t_i))]-z_{ik} + \log [\sigma(g_k(t_i))]-1-z_{ik} \quad (58)
\]

\[
\geq -\frac{1}{2} w_k^T \text{diag}(\lambda_k) + \sum_{i=1}^{M} 2\psi_i^T f(\eta_{ik}) w_k + \sum_{i=1}^{M} [z_{ik} - \frac{1}{2} \psi_i^T w_k]. \quad (59)
\]

Because it is seen that the lower bound of the approximated posterior is Gaussian distributed, the mean and covariance matrix can be easily given by rearranging the above equation to the canonical Gaussian distribution form, which is not further discussed for brevity.

Therefore, the updating rule of the mean and covariance matrix can be obtained as in (42) and (43).

\section*{D. Proof of Theorem 1}

Let us consider the segmented measurements in the hopping transition time, i.e., the time \( i \in [T-(P-1)/2 : T+(P-1)/2] \). It is assumed that the \( k \)-th latent parameter \( \alpha_k \) is correctly estimated for sparse signal \( x_k \) in the \( i \)-th time index. In other words, the indicator variable \( \xi_k \) equals 1. Thus, update equation for sparse signal \( x_k \) can be expressed as,

\[
\mu_i = \alpha_0 [\text{diag}(\alpha_k) + \alpha_0 \Phi^H \Phi]^{-1} \Phi^H y_i. \quad (60)
\]

The \( i \)-th measurement can be decomposed as

\[
y_i = \Phi_{11} x_{i,1} + \Phi_{22} x_{i,2}. \quad (61)
\]

The matrix \( \Phi_{11} \) is constructed from \( \Phi \) by replacing the last \( (i-T)+1+(P-1)/2 \) rows of \( \Phi \) with 0, and the matrix \( \Phi_{22} \) is also constructed from \( \Phi \) by replacing first \( (T-i)-1+(P-1)/2 \) rows of \( \Phi \) with 0. The position of the non-zero element in sparse signal \( x_{i,1} \) corresponds to the first carrier frequency index and the position of non-zero element in sparse signal \( x_{i,2} \) corresponds to the second carrier frequency index.

Substituting (61) into (60) and taking the limit as \( \alpha_0 \rightarrow \infty \), we can obtain,

\[
\lim_{\alpha_0 \rightarrow \infty} \mu_i = \text{diag}(\alpha_k)^{-1} \Phi^H (\Phi^H \text{diag}(\alpha_k)^{-1} \Phi)^{-1} \Phi_{11} x_{i,1} + \text{diag}(\alpha_k)^{-1} \Phi^H (\Phi^H \text{diag}(\alpha_k)^{-1} \Phi)^{-1} \Phi_{22} x_{i,2}. \quad (62)
\]

It can be seen from the above equation that the sparsity profile is determined by the sparsity profile of \( \text{diag}(\alpha_k)^{-1} \).

Since support of \( \alpha_k \) only corresponds to the correct carrier frequency bin in time index, only one of the summand terms on the right-hand side of (62) will be non-zero. More concretely, the estimated signal will only depend on \( \alpha_k \) and the sparse signal \( x_{k,j} \), \( j = 0 \) or 1, whose support is the same as \( \alpha_k^{-1} \). As long as \( \alpha_k \) and \( z_{ik} \) are correctly estimated, the algorithm can guarantee to provide correct time-frequency estimation.
