In this letter, photoacoustic-guided Raman spectroscopy (PARS) is proposed for a fast depth-resolved Raman measurement with accurate depth localization. The approach was experimentally demonstrated to receive both photoacoustic and Raman signals from a three-layer agar phantom based on a developed synergic photoacoustic-Raman probe, showing strong depth correlation and achieving magnitude of faster operation speed due to photoacoustic time-of-flight measurement and guidance, compared with the conventional depth-resolved Raman spectroscopy method. In addition, further combination with advanced optical focusing techniques in biological scattering medium could potentially enable the proposed approach for cancer diagnostics with both tight and fast optical focusing at the desired depth of tumor. © 2015 Optical Society of America

Raman Spectroscopy is a bond-selective spectroscopic technique based on inelastic scattering of light. It exhibits high chemical specificity and can quickly provide information on the molecular composition of a sample without labelling [1]. To further advance this technology for deep-tissue measurement, depth-sensitive techniques such as Confocal Raman Microscopy [2], Kerr-Gated Time Resolved Raman Spectroscopy [3-4], and Spatially Offset Raman Spectroscopy [5] have been studied extensively in recent years to extract depth specific chemical/diagnostic information from diffusively scattering samples. Confocal Raman Microscopy is highly preferable in various biomedical applications due to its superior spatial resolution in imaging of tissue samples. However, without prior depth information of a subsurface target, the light source has to be gradually scanned through the entire sample to locate the region of interest, rendering this technique highly inconvenient and time-consuming. Moreover, due to the strong scattering of biological tissue, the optical focusing in deep tissue is not ideal and strongly diffused, which impairs accurate localization of the sample. Therefore, it is highly expected that if the prior depth information of the sample is available, the focusing of the light will be much faster and more efficient with higher localization accuracy.

Photoacoustic (PA) sensing and imaging techniques have attracted tremendous research interest in recent years due to its breakthrough of optical diffusion limit by ultrasound detection [6-7]. Through optical absorption and thermoelastic expansion, PA signal is generated and detected by contact ultrasound transducers or noncontact laser interferometry/vibrometer methods. PA technique could readily provide depth information by the time-of-flight measurement of the PA signal for accurate localization, which enables 3D deep-tissue imaging [8-9]. Functional PA techniques are also available by exploring the optical absorption spectrum of both endogenous and exogenous absorbers using multi-wavelength laser source for oxygen saturation and lipid detection, etc. [10-13]. However, the specificity of the optical absorption is poor compared to the bond-selective Raman spectroscopy mentioned above. Therefore, a synergic integration of PA technique and Raman spectroscopy is highly demanded to deliver bond-selective specificity with fast and accurate depth localization for tissue characterization. A recent study on stimulated Raman PA imaging has proved the significant potential of combining PA and Raman, which however still suffers weak PA signal generation efficiency [14-15].

In this study, we propose a PA-guided depth-resolved Raman spectroscopy (PARS) technique to fully utilize the merits of both techniques for bond-selective specificity tissue characterization with fast and accurate depth localization. Both PA signals and Raman scattered photons from the same sample are collected concurrently to show high correlation with depth. Fast and accurate light focusing inside the sample is achieved for depth-resolved Raman spectroscopic analysis with the help of PA localization. The proposed technique is also potentially applicable to other optical measurements, such as diffuse reflectance or fluorescence measurements.

We designed and constructed a confocal PA-Raman probe as shown in Fig. 1(a). The PA system and Raman system shared the same optical focusing lens with both excitation lasers focused at the same focal point. This ensures that the collected PA signal and Raman signal are emitted from the same location of the sample, and makes it possible to use the real-time PA signal to guide the Raman signal detection. The water tank was mounted on a XYZ translation stage, which has a 26 mm translation range in each axis. The excitation source for PA signal generation was a Q-switched pulsed laser...
Preliminary experiments on the PA-guided depth-resolved Raman spectroscopy were conducted using the fabricated three-layer tissue-mimicking phantom. In the first experiment to prove the trend of PA-Raman correlation, the focusing spot of the PA-Raman probe was scanned by 26 mm in depth gradually from top to bottom with a step size of roughly 2 mm to prove the strong correlation between the PA and Raman signals. As shown in Fig. 2, when the laser focal point was scanned from location 0 mm down to 26 mm in the depth direction, the amplitudes of both PA waveform (Fig. 2(a) and Raman peak intensity (Fig. 2(b)) at a Raman shift of 1485 cm\(^{-1}\) experienced strong correlation with about 2 mm shift due to the diffusion of the Nigrosin dye towards the bottom layer. It also worked for another two Raman shift of 1075 and 1525 cm\(^{-1}\) (not shown here), i.e., both amplitudes were increasing and then decreasing caused by the focal point scanned across the phantom. The correlation factors for these three Raman shift are 0.87, 0.87 and 0.86 respectively (data at 26 mm is discarded). This motivated us to use PA signal as a guide for depth-resolved Raman spectroscopy by utilizing their strong correlation in depth due to the reason that the middle layer exhibits both strong Raman scattering and photoacoustic generation. From Fig. 2, the maximum signal strength occurred in the range of 8 mm to 10 mm. However, it is worth noting that if the depth information accuracy of 0.1 mm is required, 80-100 scanning steps just for one directional scanning will be needed to reach the maximum responses of Raman signals, which is quite time-consuming and inconvenient. To utilize the time-of-flight measurement of PA signals as prior depth information, an expedited focusing with much less scanning steps could be achieved, which is experimentally demonstrated next.

In the second experiment, the prior depth information extracted from the time-of-flight measurements of PA signals was used to guide the optical focusing for obtaining maximum Raman signals in a much faster way. Before the measurement, raster scanning of the PA-Raman probe in xyz coordinates could be performed to determine the location of the target, where maximum PA signal's amplitude and minimum PA signal arrival delay can be observed. The operation procedure included several iterative steps:

1) Both optical focal point and unfocused ultrasound transducer were positioned at d1=0 mm with a fixed ultrasound detection angle, such as 30 degree in this experiment as shown in Fig. 3(a), where d1=0 mm is the baseline, d2, d3, and d4 are the estimated depth position relative to the baseline. PA measurement was performed first to find the updated depth d2 information of the phantom by time-of-flight calculation d2=ct\(\times\)1 sin(30°)=0.5\(\times\)ct1, where c is the acoustic speed (1500 m/s), and t1 is the PA signal propagation time from the phantom's illumination spot to the transducer surface when the focal point is d1. Meanwhile, the Raman spectrum at position d1 mm was recorded (Fig. 3(a)).

2) Iteratively, the optical focal point was steered to position d2 for PA measurement to get an updated position d3, and so on (Fig. 3(b)-(c)). Finally, the depth information will be converged to d4=d2 with required accuracy e.g. 0.1 mm, which could be well differentiated.
by time-of-flight measurement of the PA signal’s profile from a 5 MHz transducer (with maximum frequency around 10MHz) without sacrificing the detection sensitivity.

The underlying reason of why this approach can work is: at each scanning step, it gives better optical focusing on the phantom, and thereafter generates sharper and stronger PA signal waveform, which consequently renders more accurate time-of-flight calculation and estimation of depth information of the phantom. Therefore, after several rounds of iteration, the PA signal will reach maximum amplitude and provide updated depth estimation, which is sufficiently accurate and close to the real targeted focal depth. Meanwhile, the Raman spectrum will also be maximized and specific to the focal depth.

As predicted by the PA-guided depth-resolved Raman spectroscopy technique described above, the measurement results in Fig. 4 verified the feasibility of the approach very well by placing the phantom 8 mm in depth. In Fig. 4(a), the first time-of-flight measurement of PA signal peak at t=9.4 µs gave the predicted depth information of d2=7.0 mm. The corresponding Raman spectrum was shown in Fig. 4(b). Then the optical focal point was steered to position d2 by the translation stage. As shown in Fig. 4(c), the second time-of-flight measurement of PA signal peak at t=10.8 µs gave the improved predicted depth information of d3=8.1 mm with higher accuracy. The corresponding Raman spectrum was shown in Fig. 4(d). Further, the focal point was steered to position d3 by the translation stage. As shown in Fig. 4(e), the third time-of-flight measurement of PA signal t=10.8 µs gave the next predicted depth information d4=8.1 mm. The corresponding Raman spectrum was shown in Fig. 4(f). It was found that d4=d3 (the error <0.1 µs with 5 MHz transducer used) indicating the depth prediction was converged and the maximum PA and Raman responses were achieved very fast in only 3 steps. If using the conventional depth-resolved Raman/Fluorescence spectroscopy method by linearly successive searching, it requires at least 80 scanning steps to reach the maximized Raman response for an accuracy of 0.1 mm calculated by 8mm/0.1mm=80 steps [17], the proposed PA-guided Raman spectroscopy approach could improve the operation speed significantly, depending on the targeted depth and scanning strategy, faster by >26 times (80/3=26.7) in this experiment.

The proposed PA-guided Raman spectroscopy approach attempts to utilize the correlation of both methods to achieve fast depth-resolved Raman measurement in an iterative way beyond the straightforward dual-modal PA-Raman combination approaches in previous literatures [18-19]. It is worth noting that although the proposed approach could provide the depth information for Raman measurement, the tight optical focusing in scattering medium is a significant and long-standing problem to be solved. In recent years, several interesting optical focusing techniques were reported to focus the light in scattering medium utilizing ultrasonic tagging and wavefront shaping [20-21]. Furthermore, utilizing PA signal as feedback to iteratively achieve the optimized optical focusing through wavefront shaping techniques has been reported [22-24]. It is expected that a seamlessly fusing our proposed PA-guided Raman spectroscopy approach with the recent developed optical focusing techniques in scattering medium will render a further promising Raman spectroscopy diagnostic tool for real clinical applications, e.g. skin cancer detection, which is still an untapped area and deserves further development as our future work.

In conclusion, we have proposed PARS: a fast depth-resolved Raman spectroscopy technique based on photoacoustic signal time-of-flight depth measurement and its strong correlation with Raman signals. After only several steps of iterative focusing, maximized Raman scattering signals could be detected by focusing the light accurately into the spot of the phantom with PA signal based depth measurement and guidance. Hence it could expedite the development of depth-resolved Raman spectroscopy technique towards skin and other deep cancer diagnostics with advanced wavefront-shaping based optical focusing techniques.
