1 The fundamental and technological progress in materials sciences and condensed matter
2 physics has led to the revolution and evolution of a variety of functional devices that
3 modernize our society and social life. Further advances, however, will largely depend on
4 novel materials, especially emergent materials with multifunctionality and their advanced
5 applications. Recently, lead halide perovskite has regained attentions for its big success in
6 photovoltaic.^[1-3] As a direct band-gap semiconductor, lead halide perovskite family exhibits
7 outstanding optical and emission properties, which are promising for flexible, low-cost
8 photonic devices including laser, light-emission devices and photodetector, *etc.*^[4-8] Through
9 structural engineering and composition tuning, the emission colour of lead halide perovskite
10 can be tuned from UV to NIR as well as a large scale of exciton binding energy tailorable
11 from several to several hundreds of meV.^[2, 9, 10] Together with well-controlled exciton
12 behaviour, the cubic lattice of the type of materials promises the achievement of high-quality
13 factor single crystalline Fabry-Pérot and whispering-gallery-mode cavities.^[4, 11] In this regard,
14 lead halide perovskite not only provides a perfect platform for us to study exciton-photon
15 interaction from weak to strong region in fundamental level, but also opens a new territory of
16 functional and high-efficient optoelectronic devices to complement traditional inorganic
17 semiconductors^[4, 5, 12, 13].

18 Single crystalline semiconductor optical micro/nano-cavities with high quality factor (Q)
19 and small modal volume are important for development of microscopic coherent laser source
20 for on-chip optical communications, high-density storage and super-resolution imaging in life
21 sciences.^[14] Semiconductor nanostructures, such as single crystalline nanowires and
22 microdisks, can serve as both gain media and optical microcavities confined by their facets,
23 which is particularly promising for high-quality small size laser sources.^[15-18] However,
24 constrained by exciton binding energy and thermal fluctuation, only handful wide-band
25 traditional semiconductors such as ZnO and GaN have stable and active excitons at room

1 temperature (Supporting Information, Fig. S1). In visible luminescent II-VI/III-V
2 semiconductors such as CdSe, ZnTe, *etc*, exciton dislocates at room temperature because of
3 thermal fluctuation and thus free carrier emission dominates which has larger optical loss than
4 exciton emission. In several ionic systems such as Cu₂O^[19], CuCl and CuBr, E_b is as large as
5 80-100 meV, while emission energy is still beyond 3.2-4.0 eV. The spectra coherence, one of
6 the most important characteristic of a laser device, is evaluated by lasing linewidth. According
7 to Schawlow-Townes equation, the lasing linewidth is constrained by cavity Q and gain
8 value of semiconductor, and the coupling efficiency of spontaneous emission into lasing
9 process.^[20] Till now, the lasing linewidth $\delta\lambda_l$ of visible nano/microlaser based on single
10 crystalline II-VI semiconductor compounds nanostructures is lower than ~ 0.25 nm
11 (Supporting Information, Tab. S1; Supporting Information Note 1)^[11, 21-24]. Although two-
12 dimensional transition metal dichalcogenide has recently been shown with exciton binding
13 energy on the order of ~ 1 eV at visible region, the thickness of mono- or few-layer structures
14 (sub-5 nm) is far below diffraction limit and unable to support a low-loss active cavity by
15 themselves^[25]. The lasing of two dimensional materials was achieved at low temperature (\sim
16 130 K) and other optical cavities were necessary, which limits the technologically
17 applications of the lasers^[25]. In organic semiconductors, Frenkel excitons are dominated with
18 binding energy of several hundreds meV, while the materials stability and poor crystallinity
19 are big concerns.^[26, 27]

20 Recently, a room temperature lasing from single crystalline organic-inorganic
21 CH₃NH₃PbBr₃ perovskite nanowires was proved. The lasing linewidth $\delta\lambda_l \sim 0.21$ nm and 0.23
22 nm at 520 and 790 nm respectively, ^[4, 11] which is slightly higher than that of II-VI/III-V
23 luminescent semiconductor compounds. Compared with the organic-inorganic lead halide
24 perovskites^[5, 7, 8], all-inorganic lead halide, such as CsPbX₃ (X=I, Br, Cl), exhibit better
25 stability, relatively larger exciton binding energy and higher emission efficiency ($\sim 90\%$)^[28, 29],

1 which promises for coherent and quantum light source^[29]. Nonetheless, solution-processing
2 synthesized colloidal CsPbX₃ quantum dots (CQDs) film random laser still suffers from low
3 spectra linewidth $\delta\lambda_l \sim 5$ nm, caused by significant scattering loss^[30]. The lasing spectra
4 coherence is improved ($\delta\lambda_l \sim 2$ nm) through embedding the CQDs into whispering-gallery-
5 mode silica spheres cavities; however the spontaneous emission coupled into the lasing
6 processes is not sufficient and the spontaneous emission background is still a problem for real
7 applications^[22]. A single crystalline cesium lead halide microcavities functioned as both gain
8 materials and optical feedback suppliers can address both problems simultaneously. However,
9 till now most of CsPbX₃ perovskite nanostructures (nanocrystals, nanowires and nanosheets,
10 *etc*) were prepared by solution processing methods and the sample thickness is smaller than
11 20 nm.^[31-33] According to optical diffraction law, the CsPbX₃ nanostructures cannot form
12 effective optical cavities and provide effective optical feedback to support amplification and
13 lasing actions by themselves.

14 In this work, we synthesized high-quality single crystalline all-inorganic cesium lead
15 halide CsPbX₃ (X=Cl, Br, I) nanoplatelets with micro-scale edge length and sub-wavelength
16 thickness using vapour-phase van der Waals epitaxy method. The as-grown luminescent
17 perovskite show intense, narrow-band, tunable absorption and emission properties in the
18 whole visible spectra region. Temperature-dependent absorption spectroscopy studies
19 demonstrate that the exciton binding energy for CsPbCl₃, CsPbBr₃ is 72 meV and 38 meV
20 respectively. Multi-colour (400-700 nm), low-threshold ($\sim 2.2 \mu\text{J}/\text{cm}^2$), high quality lasing
21 action is realized in the naturally formed single crystalline WGM microcavities. The lasing
22 mode linewidth is ~ 0.14 - 0.15 nm, which is so far the highest among single crystalline
23 semiconductor microcavities in visible region.

24 Cesium lead halide CsPbX₃ perovskite nanoplatelets were grown on muscovite mica
25 substrates using vapor transport chemical vapor deposition (CVD) method as previous

1 literature works introduced.^[34-36] Fig. 1a illustrates typical optical images of CsPbBr₃
2 nanoplatelets grown on mica substrate. The nanoplatelets are featured with well-defined
3 square shapes which are determined by the crystalline structure of CsPbBr₃. The predominant
4 square shapes of nanoplatelets originate from intrinsic cubic phase under high temperature
5 (*i.e.*, > 400 K)^[37]. The square nanoplatelets are well oriented at multiples of 90⁰, which
6 suggest the epitaxial nature of CsPbBr₃ crystals on mica. The growth mechanism is believed
7 to be van der Waals epitaxy, which has been previously discussed in detail in planar and
8 nonplanar structures grown on van der Waals substrates such as mica, graphene or boron
9 nitride by vapor phase or solution methods^[10, 34-36, 38-42]. The lateral dimension of the
10 perovskites nanoplatelets are ranging from 1.0 to 20.0 μm. Due to diffraction between the top
11 and bottom facets, the perovskite nanoplatelets show rich colors dependent on the thickness
12 ranging from 50.0 to 300.0 nm, which can be correlated from the optical images and atomic
13 force microscopy (AFM) (Fig. 1b). The size distribution may be due to the surface non-
14 uniformity of mica substrate. The perovskite nanoplatelets also show a highly smooth surface
15 with a surface roughness of only ~2.0 nm as indicated by AFM measurement (Fig. 1b), which
16 is perfectly flat in optical level. Similar well-defined structures can also be obtained on
17 CsPbX₃ with halide composition modulation, such as by altering Cl/Br ratio to obtain
18 CsPb(Cl/Br)₃ nanoplatelets and Br/I ratio to obtain CsPb(Br/I)₃ nanoplatelets. The detailed
19 growth condition is summarized in Supplementary Table 2. These CsPbX₃ nanoplatelets were
20 further characterized by powder X-ray diffraction (XRD) (Fig. 1c) in θ - θ geometry, which
21 means that only planes parallel to substrate surface contribute to XRD patterns. Three peaks,
22 which correspond to (100), (110) and (200) planes, can be well indexed to the cubic phase of
23 CsPbX₃ perovskites, while the other peaks originate from the mica substrate and the source
24 materials. Furthermore, these three peaks show blue shifts from CsPbCl₃ to CsPbI₃, which is
25 due to the increasing lattice constant. Three types of crystalline structures are reported in

1 CsPbX₃, including orthorhombic, tetragonal (*ie.*, 88°C for CsPbBr₃), and cubic polymorphs
2 (*ie.*, 130°C for CsPbBr₃).^[43, 44] While only cubic phase expected to exist above 400 K, is
3 observed for all the samples even at room temperature. In CsPbX₃ quantum dots, similar
4 phenomenon was found which was attributed to high growth temperature and large surface
5 energy.^[29]

6 All the cesium lead halide perovskites are direct band gap semiconductors. In CsPbX₃
7 perovskites, band edge states are mainly determined by inorganic PbX₆⁺ octahedron. The
8 conduction and valence band forms due to hybridization states between cation Pb and anion X
9 orbital^[45]. When the halide elemental weight increases from Cl to I, the bond strength
10 between Pb and X decreases and then the valence and conduction band moves closer, which
11 leads to the decreasing of optical band gap from 412 nm (CsPbCl₃) to 700 nm (CsPbI₃) (Fig.
12 1d).^[45, 46] The as-synthesized CsPbCl₃, CsPbBr₃ nanoplatelets show a strong and narrow
13 excitonic absorption peak with full width at half maximum (FWHM) of 80.0 meV (7.0 nm)
14 and 65.0 meV (15.0 nm) at room temperature, respectively, which implies a large exciton
15 binding energy. The room temperature PL spectra and image reveal that CsPbCl₃, CsPbBr₃,
16 and CsPbI₃ emit light at 3.00 eV (412 nm, FWHM ~ 8.0 nm, blue), 2.35eV (527 nm, FWHM~
17 20.0 nm, green), and 1.77eV (700 nm, FWHM ~30.0 nm, red), respectively. For given
18 material, apart from intrinsic exciton transition and exciton-phonon scattering the exciton
19 linewidth can be broaden by disorder, surface, defects, *etc.* ^[47, 48] The PL FWHM (8.0-30.0
20 nm) of CsPbX₃ nanoplatelets is smaller than that of highly luminescent CsPbX₃ CQDs (12.0-
21 42.0 nm) at room temperature, which suggests the high quality and good optical/excitonic
22 properties of as-grown nanoplatelets^[29, 49, 50]. Bandgap engineering is achieved by
23 compositional modulation, specifically, by tuning the Cl/Br ratio for the 410-527 nm range,
24 and Br/I ratio for 527-700 nm range, which almost covers the entire visible spectral region
25 (Supporting Information, Fig. S2).

1 A detailed temperature-dependent absorption spectroscopy was conducted to study the
2 exciton dynamics of the inorganic semiconductor perovskites. Fig. 1e shows the band edge
3 absorption spectroscopy of CsPbCl₃ as the temperature decreases from 350 to 77 K as a
4 typical example. Temperature dependent absorption spectroscopy of CsPbBr₃ could be
5 obtained in Supporting Information (Fig. S3). Strong exciton peak near the band edge can be
6 resolved even at 350 K. In general, spectra linewidth of exciton absorption can be attributed to
7 inhomogeneous and homogenous broadening.^[47, 48] The inhomogeneous broadening mostly
8 due to disorder is temperature-independent, which will not be considered here. On the other
9 hand, the homogenous broadening includes two contributions: 1) nature population relaxation
10 of excited states including both of radiative and non-radiative recombination; 2) elastic
11 scattering events such as exciton-exciton, exciton-phonon processing. As shown in Fig. 1f,
12 when the temperature decreases from 310 to 77 K, the exciton absorption peak becomes
13 narrower; the peak intensity increases (supplementary information Fig. S3). The phenomena
14 suggest that exciton dislocation is predominated by exciton-phonon inelastic scattering.^[48]
15 Based on the model, the linewidth of exciton absorption peak can be written as a function of
16 temperature *via* $\delta V = \delta V_0 + V_T e^{-E_b/k_B T}$. In the equation, δV , δV_0 , V_T , E_b , k_B is the bandwidth of
17 exciton peak, temperature-independent broadening, temperature dependent broadening,
18 exciton binding energy and Boltzmann constant, respectively.^[48] As shown in Fig. 2a, the
19 FWHM of exciton peaks for CsPbCl₃ and CsPbBr₃ are extracted out, which can be well fitted
20 by the above equations (Fig. 1f, Supporting information Fig. S3). Exciton binding energy E_b
21 evaluated from fitting is 38 ± 3 meV and 72 ± 3 meV for CsPbBr₃ and CsPbCl₃, respectively.
22 The value is in good agreement with previous calculation results.^[29] Since exciton absorption
23 peak of CsPbI₃ could not be resolved at room temperature, a calculation value of ~ 20 meV
24 from previous work was adopted in this work.^[29] The binding energy decreases from 73 to *c.a.*
25 20 meV with the increase of halide elemental weight and the reduction of band gap from Cl to

1 I, which could be simply explained by perturbation theory.^[51] The large exciton binding
2 energy ($E_b > 25$ meV) confirm that in the as-grown all-inorganic lead halide perovskites
3 exciton is stable and does not ionize into free carriers at room temperature, which well
4 explains the observations of sharp exciton absorption peak and narrow band emission in
5 absorption and emission spectroscopy (Fig. 1). The exciton binding energy of CsPbX₃
6 perovskite is relatively higher than II-VI and III-V semiconductors in the same spectra range
7 (Supporting Information, Fig. S1). The underline reason is still unclear and further studies are
8 needed.

9 The CsPbX₃ crystals with sub-wavelength thickness and uniform square shape naturally
10 form high-quality whispering-gallery-mode microcavities. To probe the cavity performance
11 for amplification and oscillations, we conducted lasing characterization with the nanoplatelets
12 as schematically shown in Fig. 2a. At low pump fluence the band edge emission (FWHM: 20
13 nm, center wavelength: 527 nm) is too weak to be resolved in the same scale of the spectra
14 taken above lasing threshold (Fig. 2a). When the pump fluence increases (~ 1.5 $\mu\text{J}/\text{cm}^2$),
15 narrow oscillation peaks can be observed around $\lambda = 530.0$ nm, which are the optical modes
16 selectively amplified by the optical feedback in the square cavity. At a pump fluence of 2.5
17 $\mu\text{J}/\text{cm}^2$ per pulse, the oscillation peak intensity increases sharply together with the further
18 narrowing of peak width $\delta\lambda$, indicating the occurrence of lasing action. As the pumping
19 fluence reaches 3.0 $\mu\text{J}/\text{cm}^2$, the lasing linewidth (FWHM) is as small as $\delta\lambda = 0.15$ nm. The
20 laser linewidth is relatively smaller compared to previous reports in semiconductor
21 microcavities ($\lambda_l \sim 0.2$ nm). (Supporting Information, Tab. S1). The peak emission intensity
22 versus excitation power (input-output curve) shows a typical “S” shape which confirms lasing
23 action based on a multi-mode laser theory (Fig. 2d). The linear region at low pumping power
24 is attributed to spontaneous emission, the superlinear increase region above 2.2 $\mu\text{J}/\text{cm}^2$
25 suggests amplified spontaneous emission while the further linear increase region at higher

1 pump fluence demonstrates a full lasing action. The transition of linear region (spontaneous
2 emission) towards nonlinear region (stimulated emission) occurs at $P = 2.2 \mu\text{J}/\text{cm}^2$ which can
3 be assigned as the lasing threshold. The carrier density at the threshold *c.a.*, $\sim 1.5 \times 10^{17} \text{cm}^{-3}$,
4 which is smaller the Mott density of CsPbBr_3 ($\sim 1.8 \times 10^{17} \text{cm}^{-3}$), suggesting that the
5 amplification of radiation is corresponding to excitonic lasing.^[52] The slight blueshift of ~ 0.5
6 nm under intense pumping may be due to the reduction of refractive index.^[52] The detailed
7 mechanism needs further investigations.

8 Further investigations into the remarkable performance of the CsPbBr_3 platelet are
9 conducted with time-resolved photoluminescence (TRPL) measurements (see Fig. 2e). The
10 spontaneous emission lifetime is as long as $\tau_{\text{SPE}} \sim 4.2$ ns at low excitation ($\sim 0.1P_{\text{th}}$, navy dots).
11 The τ_{SPE} decreases to ~ 3.0 ns at higher excitation fluence ($\sim 0.8P_{\text{th}}$). When the excitation
12 fluence is above the threshold ($\sim 1.2P_{\text{th}}$), very fast time decay (< 30 ps, limited by the streak
13 camera instrument response) dominates the kinetic process, further signifying the stimulated
14 emission process and supporting the lasing occurrence in the square cavity.

15 We explore the optical modes inside the cavity. At the thickness of 180 nm, both of
16 Fabry-Pérot (FP) mode oscillation between two facets and WGM oscillation among the four
17 facets are possible. However, the gain threshold of FP mode is much larger than that of WGM
18 oscillation. Therefore, primarily the lasing observed in experiment is considered to be due to
19 WGM lasing. Further photoluminescence/lasing image and field calculations are conducted.
20 Fig. 3a-3b shows the photoluminescence image of individual CsPbBr_3 below and above lasing
21 threshold, respectively. When the excitation fluence is lower than the lasing threshold, the
22 whole platelet body exhibits green color, suggesting the unidirectional out-coupling of
23 spontaneous photoluminescence emission. While the excitation fluence is higher than the
24 lasing threshold, the spontaneous emission is selected and confined by the whispering-gallery-
25 mode cavity, large amount of photons can only emit from the square cavity edges, resulting in

1 a significantly stronger emission at the nanoplatelet edge and particularly at the corners. This
2 pattern agrees very well with the electric field distributions of transverse mode (TM)
3 calculated based on whispering-gallery-mode cavity using a finite domain time difference
4 (FDTD) package (Fig. 3c). The calculation shows that the optical field at the resonance mode
5 is well confined inside the microcavity in the form of WGM oscillation. The field has more
6 leakage at four corners; therefore experimentally far-field emission image shows strong
7 intensity in these areas.

8 We further investigate the lasing mode as a function of the nanoplatelet edge. With the
9 increasing of nanoplatelet edge length L from 9.0 to 29.0 μm , the spacing between two
10 adjacent mode decreases from to 3.0 nm to 0.9 nm (Fig. 3d). To rule out the influence of
11 thickness difference on effective index around diffraction limit, CsPbBr₃ nanoplatelets with
12 similar thickness (180 ± 20 nm) were selected. The mode spacing extracted from Fig. 3d
13 exhibit is linear proportional to the inverse of edge length (Fig. 3c-d). In a cubic WGM
14 resonator, the mode spacing $\delta\lambda_l$ can be written as^[53]:

$$15 \quad \delta\lambda_l = \frac{\lambda_l^2}{2\sqrt{2}Ln_g},$$

16 A group refractive index n_g of ~ 3.7 is extracted out through the fitting, which show good
17 agreement with previous studies, suggesting the achievement of whispering-gallery-mode
18 lasing.^[24] The lasing peaks usually locate at the lower energy side of spontaneous emission,
19 which is widely observed in II-VI and III-V semiconductor microlasers. The phenomenon is
20 assigned to exciton self-absorption during the photon propagation process along the cavity.^[15]
21 With the increasing of edge length, a small redshift of lasing peaks (~ 1.0 nm) was observed
22 through compared the center frequency of the lasing modes, which also supports the
23 occurrence of self-absorption.

1 Multi-color lasing actions can be realized in ternary and quaternary perovskite square-
2 shaped platelet crystals at room temperature, as shown in Fig. 4a. When spontaneous emission
3 colour of gain materials is tuned from blue to red through element modulation, the lasing
4 threshold is around $\sim 2.0\text{-}10.0 \mu\text{J}/\text{cm}^2$, which is comparable with traditional semiconductors
5 and smaller than CsPbX₃ QDs WGM laser with much larger size as reported recently^[15, 22].
6 The PL images (inset, Fig. 4a) above lasing threshold clearly show the predominance of
7 whispering-gallery-modes lasing. The lasing peak is much stronger than their spontaneous
8 emission background, indicating that large amount of spontaneous emission participates in
9 lasing process. The high quality of square cavity and emission quantum yield are sustained for
10 quaternary CsPbX₃ compounds. Fig. 4b displays zoom-in spectroscopy of one lasing mode for
11 quaternary lead halide CsPb(Br/I)₃ perovskite with a centre emission wavelength of ~ 680 nm
12 (Fig. 4b). In the solid state crystalline lasers, inhomogeneous broadening, such as Doppler and
13 pressure broadening could be neglected.^[54] The homogenous broadened lasing peak could be
14 well fitted by a Lorentz function with FWHM of 0.14 nm.^[25] The slight asymmetric profile is
15 due to background subtraction. The laser linewidth is smallest among any single crystalline
16 inorganic semiconductors and other perovskite microcavities in this spectra range (Supporting
17 Information, Tab. S1). It should be noted that the laser linewidth of the as-grown perovskites
18 is compared with or slightly lower than that of microlasers manufactured by embedding the
19 semiconductor nanostructures into other ultra-low loss optical cavities such as silica
20 whispering-gallery-mode cavities or distributed Bragg reflector cavities.^[55, 56] It could be
21 predicted that the laser linewidth of the all-inorganic perovskite micro-laser can be further
22 promoted via introduction of the other high-*Q* passive optical cavities using similar methods.
23 The high spectra coherence performance of as-fabricated microlaser can be attributed to
24 room-temperature stable exciton as a result of large exciton binding energy, naturally formed
25 cubic WGM mode resonator and promising highly luminescent gain materials.

1 To conclude, we demonstrate all-inorganic whispering-gallery-mode crystalline micro-
2 cavities using van der Waals epitaxy cesium lead halide CsPbX_3 ($X=\text{Cl, Br, I}$), which show
3 intense, high quality room-temperature spontaneous emission lasing tuned over the entire
4 visible region (410-700 nm). Multi-colour, low-threshold lasing is realized in individual all-
5 inorganic perovskite microcavities with promising spectra coherence. More efforts should be
6 put on light-emission and electrically driven nanolaser sources development and also
7 fundamental studies in macroscopic quantum optics such as exciton-photon polariton and
8 polariton lasing.

9

1 **Experimental Section**

2 *Synthesis of CsPbX₃ and characterization*

3 The compounds CsPbX₃ perovskite nanoplatelets were grown by a vapour transport method
4 using a home-built chemical vapour deposition (CVD) system. The substrate muscovite mica
5 is cleaned by acetone and put inside the downstream of a quartz tube mounted in a single zone
6 furnace (Lindberg/Blue MTF55035C-1). The source is mixed powder of lead halide PbX₂ and
7 CsX with molar ratio 1:1. After the substrate and sources are placed inside the quartz tube, the
8 quartz tube is pumped down with a setting base pressure of 50 mTorr, which is followed by a
9 30 sccm flow of high purity N₂ (99.999 %). The temperature and pressure inside the quartz
10 tube are then set and stabilized for 20 minutes. For CsPbCl₃, CsPbBr₃, CsPbI₃, the
11 temperature and pressure are 625 °C and 100 Torr, 575 °C and 50 Torr, 550 °C and 100 Torr,
12 respectively. After the synthesis, the tube is cooled down naturally. The crystalline structure
13 of as-grown nanoplatelets is characterized by x-ray diffraction (XRD, Bruker D8 advanced
14 diffractometer, Cu K α radiation). The size and thickness of the nanoplatelets are measured by
15 scanning electron microscopy (SEM, JEOL JSM-7001F) and atomic force microscope (AFM,
16 Veeco Dimension V).

17 *Optical characterizations*

18 The absorption spectroscopy of absorption spectroscopy was conducted on PerkinElmer
19 Lambda 950 UV/Vis/NIR spectrometer. Steady-state photoluminescence was performed on a
20 confocal micro-spectrometer using reflective symmetry (Horiba-JY T64000). For CsPbBr₃ to
21 CsPbI₃ sample, A solid state diode laser 473 nm was focused by an objective (100 \times , NA: 0.9)
22 to excite the samples. The pumping power is 22 μ W. For CsPbCl₃ and CsPb(Cl/Br)₃, a UV
23 325 nm laser is focused by 20 \times UV objective as excitation source (power: 10 μ W). The lasing
24 and time-resolved PL spectroscopy was carried out on a home-built far-field epi-fluorescence

1 microscope at room temperature in a vacuumed atmosphere. A 400 nm pulsed laser was used
2 as the excitation source, which was frequency doubled by a BBO crystal from an amplifier
3 laser source (Libra, Coherent company, center wavelength: 800 nm, repetition rate: 1 kHz,
4 pulse width: 50 fs). The pump light was focused by a microscopy objective (20×, NA: 0.45)
5 and excited on the samples. The excitation laser spot was expanded (around 25 μm in
6 diameter) to excite the whole nanoplatelets to minimize heat and optical damage at high
7 energy pumping condition and promote energy injure efficiency. The emission signal was
8 collected the same objective and analyzed by a Acton spectrometer (Spectra Pro 2500i)
9 equipped with a Princeton Instrument liquid helium cooled CCD (Pixis 400B) for lasing
10 measurement. For time-resolved photoluminescence measurement, the signal was analyzed by
11 an Optronis Optoscope streak camera system with an ultimate temporal resolution up to ~ 10
12 ps.

13 *Numerical calculations*

14 The cross-section waveguide mode properties including effective indices and field
15 distributions of nanoplatelet on top of mica were calculated using finite element method
16 (Lumerical FDTD). To simplify the system from 3D to 2D, we introduce the effective index
17 of refraction, mainly the planar waveguide model. Then, we simulate the mode distribution in
18 2D system using the effective index rather than the index of the material. The refractive index
19 of mica and perovskite can be obtained from previous literature.^[5]

11 **Figure 1 Cesium Lead Halide Perovskite Nanoplatelets.** (a) Optical image of CsPbBr₃
 12 nanoplatelets showing square or rectangular shapes and rich colors. (b) AFM characterization of
 13 individual CsPbBr₃ nanoplatelets with different colors. (c) XRD pattern of as-grown CsPbX₃
 14 nanoplatelets showing cubic phase. (d) Optical absorption (dash line) and PL spectra (solid line) of
 15 CsPbCl₃, CsPbBr₃ and CsPbI₃ nanoplatelets. Inset: PL image of CsPbCl₃, CsPbBr₃ and CsPbI₃ (left to
 16 right). (e) Temperature dependent absorption spectra of CsPbCl₃. The temperature for the curve from
 17 bottom to up is from 350 K, 330 K, 320 K, 296 K, 260 K, 230 K, 210 K, 200 K, 160 K, 120 K and 77
 18 K, respectively. (f) The full width at half maximum (FWHM) of the curve or the bandwidth of the
 19 exciton peak dependent on temperature for CsPbBr₃ (pink) and CsPbCl₃ (navy). A single exponential
 20 decrease function (lines) is used to fit the experimental data (dots). The exciton binding energy
 21 evaluated from the fitting for CsPbBr₃ and CsPbCl₃ is 38 meV and 72 meV, respectively.

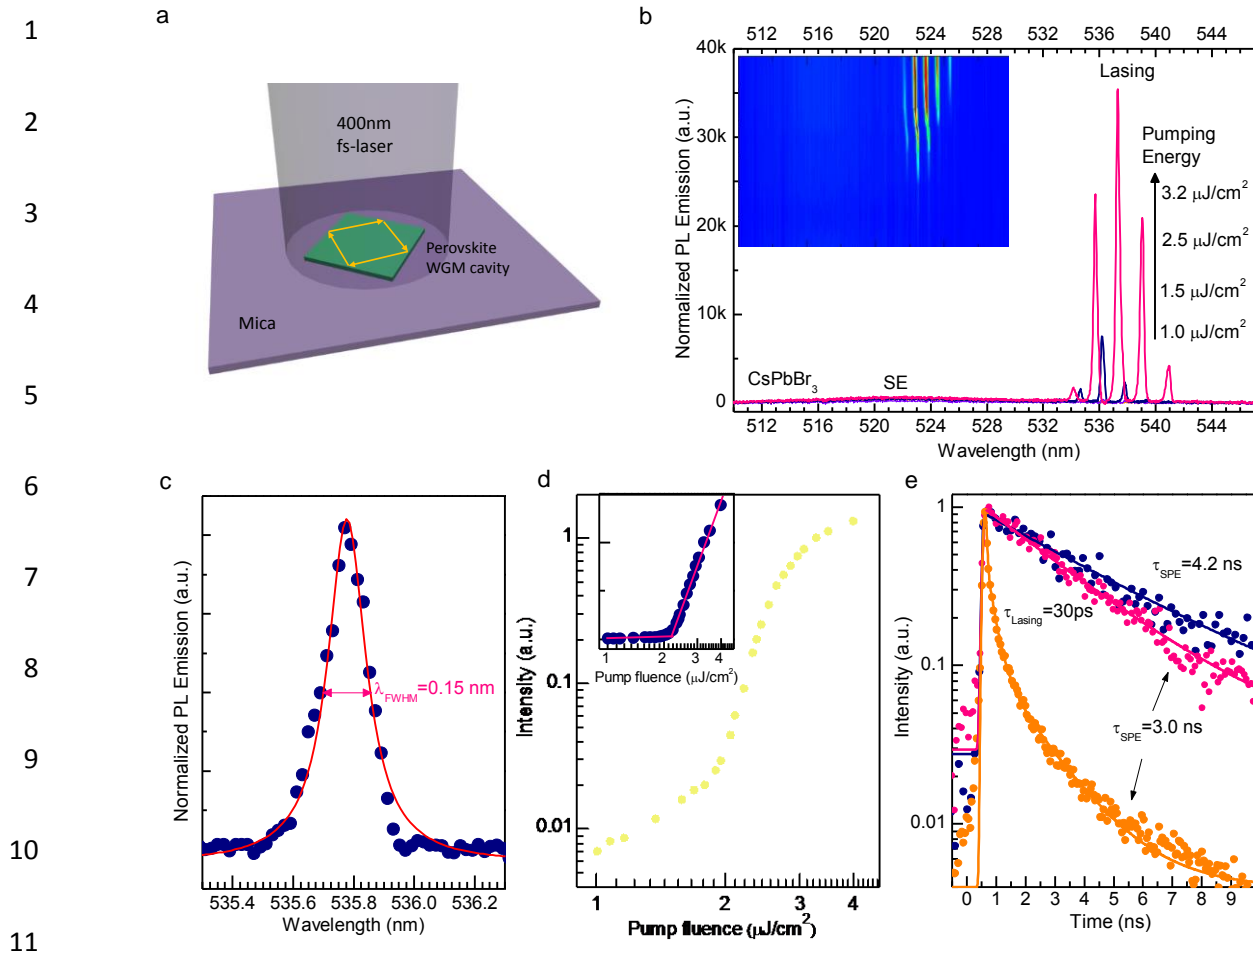

Figure 2 Lasing Characterization of Cesium Lead Halide Nanoplatelets. (a) Schematic of a CsPbX₃ (X= Cl, Br or I) plate on mica substrate pumped by a 400 nm laser excitation (~50 fs, 1 kHz). The yellow line indicates the light propagation inside the cubic WGM cavity. (b) Emission spectra at five different optical pump fluencies, showing the transition from spontaneous emission to amplified spontaneous emission and to lasing. Inset: 2D pseudo-color plot of the plate emission spectra under different pump fluence (P) showing a broad SPE peak below the threshold (P_{th}) of $\sim 2.2 \mu\text{J}/\text{cm}^2$.pulse and a series narrow lasing peaks above the threshold. (c) A Lorentz fitting of a lasing oscillation mode. The FWHM is 0.15 nm. (d) Nonlinear response of laser output power with increasing pump fluence, showing threshold region as a ‘kink’ between the two linear regions of spontaneous emission and lasing (Inset). The lasing energy at the ‘kink’ (P_{th}) is of $\sim 2.2 \mu\text{J}/\text{cm}^2$.pulse. (e) TRPL decay kinetics after photoexcitation with pump fluence below ($P \sim 0.8P_{th}$) and above threshold ($\sim 1.2 P_{th}$), showing a ~ 3.0 ns SPE decay process below P_{th} and a <30 ps lasing process above P_{th} . A lifetime of ~ 4.2 ns is shown at relatively low pump fluence ($\sim 0.1 P_{th}$).

Figure 3 Whispering-Gallery-Mode Characterization and Numerical Calculation. (a-b) Photoluminescence emission image captured by a charge coupled detector using a reflective symmetry below (a) and above (b) lasing threshold for an individual CsPbBr₃ perovskite nanoplatelet. The thickness and the edge length of the nanoplatelet is around 180 nm and 9 μm, respectively. The scale bar is 3 μm. The excitation laser is a femto-second laser with wavelength of 400 nm and spot size is large enough to illuminate the whole nanoplatelet. The green color shows photoluminescence coupled out from the nanoplatelet. Below the lasing threshold, the whole body of nanoplatelet is in green, indicating unidirectional spontaneous emission. Above the lasing threshold, the edge emission is much stronger than the center area and the four corners have strongest emission, suggesting the confinement effect and mode selection by the whispering-gallery-mode cavity. (c) Simulated electric field distribution inside the square perovskite cavity under a transverse magnetic resonant mode. The pattern shows that whispering-gallery-mode is supported by the cavity. Four corners show the strongest out-coupling or leakage compared with the other places. (d) Multi-mode lasing spectroscopy of four nanoplatelets with different edge length from 9 to 29 μm. The oscillation number of lasing mode (9 μm) is indicated along with the spectroscopy. The edge length is indicated nearby each spectroscopy. The selected four nanoplatelets have similar thickness nanoplatelets are almost the same (±20 nm). The spacing between two adjacent modes decreases with the increasing of edge length. (e)

1 The mode spacing is extracted out and plotted as a function of the inverse of edge length. Navy dots
 2 are experimental data. Navy line is the linear function fitting of the experimental data.
