I. INTRODUCTION

Three-dimensional (3D) Weyl semimetals (WSMs) are prototypical topological metals, featuring one or more pairs of protected band degeneracy points in the Brillouin zone [1–7]. These “Weyl points” act as quantized sources and sinks of Bloch band Berry flux [8]. The nontrivial bulk band topology is manifested in the appearance of peculiar branches of gapless states bound to certain exposed surfaces, featuring open segment Fermi surfaces, i.e., “Fermi arcs” [see Fig. 1(a)] [1–6,9]. At the single particle level, these unusual features are responsible for a variety of intriguing transport phenomena [10–17].

Here we show that the coupled, collective dynamics of electrons on both the open-segment and closed WSM Fermi surfaces sharply departs from that expected in conventional metals. This unusual situation gives rise to “Fermi arc plasmons” (FAPs), which are confined to certain exposed surfaces and are characterized by highly anisotropic dispersions [Figs. 1(b) and 1(c)]. In conventional metals, surface plasmons are nearly dispersionless and feature closed, elliptical constant frequency contours. As a result, a large range of surface plasmon wave vectors can be supported at a given frequency, with corresponding group velocity vectors directed along a few specific collimated directions. Fermi arc plasmons can be probed using near-field photonics techniques, which may be used to launch highly directional, focused surface plasmon beams. The unusual characteristics of FAPs arise from the interplay of bulk and surface Fermi arc carrier dynamics and give a window into the unusual fermiology of Weyl semimetals.

In the recently discovered Weyl semimetals, the Fermi surface may feature disjoint, open segments—the so-called Fermi arcs—associated with topological states bound to exposed crystal surfaces. Here we show that the collective dynamics of electrons near such surfaces sharply departs from that of a conventional three-dimensional metal. In magnetic systems with broken time reversal symmetry, the resulting Fermi arc plasmons (FAPs) are chiral, with dispersion relations featuring open, hyperbolic constant frequency contours. As a result, a large range of surface plasmon wave vectors can be supported at a given frequency, with corresponding group velocity vectors directed along a few specific collimated directions. Fermi arc plasmons can be probed using near-field photonics techniques, which may be used to launch highly directional, focused surface plasmon beams. The unusual characteristics of FAPs arise from the interplay of bulk and surface Fermi arc carrier dynamics and give a window into the unusual fermiology of Weyl semimetals.

The Fermi arc plasmon dispersion has three chiral branches, featuring hyperbolic frequency contours over a wide bandwidth. These modes arise from the hybridization of conventional surface plasmons, supported by bulk free carriers, and collective modes of carriers in the topological surface states. The ordinary surface plasmon frequency is denoted by $\omega_{surf}$, and topological surface states are characterized by the velocity $v_{s}$. The Fermi arc plasmon frequency is denoted by $\pm \omega_{inf}$, and topological surface states are characterized by the velocity $v_{in}$.

We expect that FAPs can be realized in WSMs that break time-reversal symmetry (TRS), such as candidate magnetic WSMs [1–3,20–26]. FAPs in such materials provide a novel intrinsic realization of hyperbolic plasmons that are traditionally associated with artificially engineered metamaterials [27]. Previous studies have revealed a number of interesting plasmonic phenomena, including nonreciprocity [28,29] and signatures of the chiral anomaly [10,16,29–31] associated with the collective behavior of carriers on the (closed) bulk Fermi
surfaces of WSMs [32–34]. Here we aim to expose the new collective phenomena that arise due to WSM chiral Fermi arcs. In so doing, we adopt a phenomenological approach, concentrating on the universal features of WSMs that are not tied to a specific microscopic model.

II. COLLECTIVE CARRIER DYNAMICS

To begin, we examine collective charge carrier dynamics in a 3D WSM in a semi-infinite slab geometry, occupying the region $z < 0$, see Fig. 1(b). For concreteness, we consider a model dispersion with two bulk Weyl nodes at zero energy, situated at points $(0, \pm k_z, 0)$ in the Brillouin zone (i.e., separated along the $k_y$ direction) [35]. For each fixed value of $k_y$ with $|k_y| \ll k_z$, the two-dimensional dispersion $\varepsilon_{2D}(k_x,k_y;k_z)$ is gapped, with upper and lower bands featuring Chern numbers $-1$ and $+1$, respectively. At the surface $z = 0$, this nontrivial topology yields a branch of gapless chiral surface states for each $|k_y| < k_z$. When the Fermi energy is close to zero, the filling of the chiral surface states is characterized by an open segment Fermi surface—the “Fermi arc” (see Fig. 1(a), and Refs. [1–3]). As we show, these Fermi arc carriers bring dramatic new features to WSM surface plasmons.

To describe FAPs in the slab geometry, it is useful to partition the particle density field $n$ and the particle current density field $\mathbf{v}$ into bulk and surface contributions. For each Fourier mode with angular frequency $\omega$, we write the following:

$$
n(\mathbf{r}, \omega) = n_b(\mathbf{r}, \omega)\Theta(–z) + n_s(\mathbf{r}, \omega)\delta(z),$$

$$\mathbf{v}(\mathbf{r}, \omega) = \mathbf{v}_b(\mathbf{r}, \omega)\Theta(–z) + \mathbf{v}_s(\mathbf{r}, \omega)\delta(z).$$

(1)

Here the $s$ and $b$ subscripts of $n_{s,b}$ and $\mathbf{v}_{s,b}$ denote surface and bulk contributions, respectively, and $\mathbf{r} = (x,y)$ is the two-dimensional coordinate on the surface $z = 0$. The surface densities $n_s$ and $\mathbf{v}_s$ account both for surface charges that may build up from the motion of bulk-free carriers [36] and for the behavior of carriers in the unconventional topological surface states; $\mathbf{v}_s$ is always oriented within the plane of the two-dimensional surface, so that $v_y = 0$. We note, parenthetically, that in addition to the current described in Eq. (1), magnetic systems also possess magnetization currents. These currents, however, do not contribute to transport [37,38] and cannot affect particle density since they are inherently divergence free; they do not affect the FAP dispersion we focus on here.

We note that in accounting for $n(\mathbf{r}, \omega)$, we assume smooth density inhomogeneity (characterized by small wave vector $q$) as well as low doping, $q,k_F \ll k_z$. As a result, the dynamics are dominated by Fermi arc carriers with momenta far from the Weyl cones, with wave function profiles that are exponentially localized near the surface [1,12]; since $k_z$ is an $O(1)$ fraction of inverse lattice constant, there is a large window of applicable $q,k_F$.

The bulk carrier density obeys the continuity relation

$$ione_b + \nabla \cdot \mathbf{v}_b = 0, \quad e\mathbf{v}_b(\mathbf{r}, \omega) = \mathbf{\sigma}(\mathbf{r}, \omega)[–\nabla \phi(\mathbf{r}, \omega)],$$

(2)

where $\mathbf{\sigma}(\mathbf{r}, \omega) \propto \Theta(–z)$ is the bulk conductivity tensor, $\phi$ is the electric potential, and $e = –|e|$ is the electron charge. The conductivity $\mathbf{\sigma}(\omega)$ includes an intrinsic anomalous Hall component $\sigma_H = \sigma_{sz} = –\sigma_{sz}$, due to the Berry flux between the Weyl nodes [18], and a longitudinal part $\sigma_{xx} = \sigma_{yy} = \sigma_{zz}$. At low doping, $\sigma_H$ is dominated by regions far from the Weyl nodes; here we estimate $\sigma_H = e^2/(2\hbar)$ [18,39].

At the surface $z = 0$, the continuity relation for the surface density picks up a source term arising from bulk currents impinging on the surface:

$$ione_s(\mathbf{r}, \omega) + \nabla \cdot \mathbf{v}_s(\mathbf{r}, \omega) = \mathbf{\hat{z}} \cdot \mathbf{v}_b|_{\partial z}.$$  

To arrive at Eq. (3), we have used Eq. (1) and the full continuity equation, along with $\partial \phi(–z) = –\delta(z)$. Plasmons emerge from Eqs. (2) and (3) as self-sustained collective oscillations, with the electric potential generated internally by density fluctuations $\delta n(\mathbf{r},\omega) = n(\mathbf{r},\omega) – n_0$. Here $n_0$ is the equilibrium electron density.

As in a conventional metal, bulk carriers (denoted $M$) may pile up at a surface when the system is pushed out of equilibrium, giving a surface density contribution $n_s = n_s^M$ [40]. In equilibrium, $n_s^M \equiv 0$. Importantly, the associated surface particle current density, $\mathbf{v}_s^M$, vanishes at linear order in the deviation from equilibrium (see Appendix [35]). In the linear regime, Eq. (3) together with the nonretarded Coulomb interaction yields the familiar nondispersive surface plasmon mode of a 3D metal [41].

For the WSM, in addition to the conventional surface density $n_s^M$, we must also account for the dynamics of carriers in the topological surface states (denoted $F$). We thus express the total surface density as $n_s(\mathbf{r},t) = n_s^M(\mathbf{r},t) + n_s^F(\mathbf{r},t)$ [40], where $n_s^F(\mathbf{r},t)$ is the Fermi arc surface state density distribution [see Figs. 1(a) and 1(b)]. Here $n_s^F$ includes all electrons in the topological surface states up to the Fermi arc and is thus sensitive to details of the dispersion far below the Fermi surface. However, the electrodynamic response only depends on deviations from equilibrium, i.e., deformations of the Fermi arc.

The topological surface states carry a finite (in-plane) surface particle current density, analogous to the persistent currents that flow in quantum Hall edge states. For a straight Fermi arc with $k_z$-independent dispersion, $\varepsilon_s(k_x,k_z) = \varepsilon_0 k_z$, the surface particle current density is proportional to $n_s^F$ and oriented along $\hat{x}$. Here $v_{s,x}$ is the velocity of the chiral surface states on the surface $z = 0$; it has the same sign as $\sigma_H$ [35]. For a more general topological surface state dispersion [5,6], nonequilibrium deformations of the Fermi arc may also lead to currents parallel to $\hat{y}$, similar to a conventional 2D system with a closed Fermi surface. We account for Drude-like dynamics along $\hat{y}$ using a phenomenological Drude weight $\tilde{D}$ [35] and write:

$$\mathbf{v}_s(\mathbf{r},t) = [i\hbar n_s^F(\mathbf{r},t)]\hat{x} + \left[\frac{D}{ie\omega}(-\partial_t \phi(\mathbf{r},t))\right]\hat{y}.$$  

(4)

Note that $D \equiv 0$ for a system with $k_z$-independent surface state dispersion.

We now analyze the surface density dynamics, Eq. (3). We focus on the collisionless limit, $\omega \gg 1/\tau_{surf}$, where $\tau_{surf}$ is a relaxation time characterizing the scattering between $F$ and $M$ species on the surface. In this limit, $n_s^F$ and $n_s^M$ obey separate continuity equations:

$$i e\omega n_s^M + \sigma_{sx} \nabla_x \phi|_{\partial z} = 0,$$

$$i e\omega n_s^F + \sigma_{sx} \nabla_x \phi + e\nabla \cdot \mathbf{v}_s = 0.$$  

(5)
The two fluids $M$ and $F$ are coupled by the Coulomb interaction, encoded in $\phi(r, \omega)$. For momenta very close to the Weyl nodes, the $F$ and $M$ carriers are not sharply distinguished. However, for $k_r \gg k_F$, and in the linear regime, $v_s$ is dominated by $F$ carriers far from the Weyl nodes where the distinction is clear.

Notice that the surface density dynamics is explicitly coupled to bulk currents in Eq. (5). In particular, $\sigma_{xx} \nabla_x \phi |_0$ captures the current density of bulk free carriers impinging on the metal surface from $z < 0$. Similarly, $\sigma_{xx} \nabla_x \phi$ accounts for the fact that an in-plane electric field induces changes in the topological surface state density, via anomalous Hall currents associated with undergrad carriers at momenta far from the Weyl nodes.

### III. FERMI ARC PLASMONS IN A WEYL SEMIMETAL

FAPs arise as surface-bound plane wave solutions to the equations of motion (1)–(5), of the form $\delta n_s(r, \omega) \sim e^{i \omega t - i q \cdot r}$. Here $q = (q_x, q_y)$. Below we algebraically eliminate the particle density and current density fields from the equations of motion, obtaining a compact description of the coupled motion of surface and bulk carriers in terms of $\phi(r, \omega)$. Away from the surface at $z = 0$, the Fourier modes $\tilde{\phi}_q(z)$ inside ($<$) and outside (>) the WSM obey the Poisson equation (in the nonretarded limit):

\[
(q^2 - \partial_z^2) \tilde{\phi}_q(z) = \frac{4\pi e}{\kappa} \tilde{n}_{b,q}(z), \quad (q^2 - \partial_z^2) \tilde{\delta}_q(z) = 0,
\]

where $q = |q|$, and $\kappa$ is the background dielectric constant in the WSM (the region denoted $>$ is vacuum); the $\omega$ dependencies of $\tilde{\phi}_q$ and $\tilde{n}_{b,q}(z)$ are implicit. We eliminate $\tilde{n}_{b,q}(z)$ from Eq. (6) using Eq. (2) and obtain solutions $\tilde{\phi}_q(z) = \alpha_q e^{\kappa z}$, $\tilde{\delta}_q(z) = \beta_q e^{-\kappa z}$. We note that for $q \ll k_s$, $\phi(z)$ falls off much more slowly than the Fermi arc carriers, justifying our neglect of their width.

To determine the plasmon potential $\tilde{\phi}_q(z)$, we must specify appropriate boundary conditions at the surface $z = 0$. First, $\tilde{\phi}_q(z)$ must be continuous at $z = 0$. Second, note that FAPs involve a dynamical modulation of the surface charge density, $e n_s$. As a result, the electric displacement field across the surface exhibits a jump:

\[
\partial_z \tilde{\phi}_q |_{z=0} - \kappa \partial_z \tilde{n}_{b,q} |_{z=0} = -4\pi e \delta n_s q.
\]

Here we use $\delta n_s = \delta n_{s,M} + \delta n_{s,F}$, with $n_{s,M}(r, \omega) = n_{s,F}(r, \omega) = \chi = [M, F]$. Superscript $(0)$ denotes the equilibrium carrier densities. Note that there is no jump in the displacement field in equilibrium.

To obtain a closed set of equations for the potential $\tilde{\phi}_q(z)$, we must eliminate $\tilde{n}_{b,q}$ from Eq. (7). Using Eq. (5) with Eq. (4) for a plane wave, we relate the surface density fluctuations to the electric potential $\tilde{\phi}_q$:

\[
\tilde{\delta}_{s,q} = G^s \tilde{\phi}_q, \quad G^M = -\frac{q \sigma_{xx}}{i \epsilon \omega}, \quad G^F = \frac{q \sigma_{xx} + \frac{1}{2} q_x^2}{e (\omega - v_0^q q_x)}.
\]

Note that the chirality of the Fermi arc carriers is exhibited in Eq. (8) through the pole in $G^F$, which arises for a single value of $q_x$ for a given $\omega$.

Using Eq. (8) in Eq. (7), and the explicit forms for $\tilde{\phi}_q(z)$ and $\tilde{\delta}_q(z)$, we seek the values of $q$ and $\omega$ such that the boundary conditions on $\tilde{\phi}_q$ and $\tilde{\delta}_q$ are satisfied. This yields the FAP dispersion relation:

\[
(\omega - v_0^q q_x) \left[ \frac{k + 1}{\kappa} - \frac{\omega^2}{\omega^2 - \sigma_{H} - \frac{4\pi D q_x^2}{\kappa \omega q}} \right] - 4\pi e \delta n_s q_x = 0.
\]

Here we have used $4\pi \sigma_{xx}/\kappa = \omega_{pl}^2/(i \omega)$, valid in the collisionless limit; $\omega_{pl}$ is the bulk plasmon frequency.

### IV. CHARACTERISTICS OF FERMI ARC PLASMONS

The roots of Eq. (9) yield the frequencies of Fermi arc plasmons. We find three distinct branches of solutions (labeled 1, 2, and 3), as shown in Fig. 1(c) and Fig. 2. These branches arise from the hybridization of conventional dispersionless surface plasmons with the collective excitations in the topological surface states. The hybridization is controlled by $\sigma_H$ and $D$, which couple the bulk and surface densities [see Eqs. (4) and (5)]. We note that branch 3 is related to branch 1 via the transformation $\omega \rightarrow -\omega$ and $q \rightarrow -q$. However, at each $q$ there are three distinct solutions, associated with modes with different velocities.

We note that the qualitative features of FAPs discussed here do not depend on the specific parameter values; rather, they arise from the defining features of WSMs. For illustration, in modeling Fig. 1 and Fig. 2, we have used the physically reasonable parameters $\sigma_{H} = 2.0$, and $D = 6.0$ [5,6,20]. For a detailed discussion of ball park parameter value estimates see Appendix [35].

In Fig. 2(a) we show a contour plot of the dispersion relation of the FAP branch labeled 1 in Fig. 1(c). Interestingly, most
of these contours are open and resemble hyperbolae: at large \(|q|\), the open contours asymptotically approach the line \(\theta = \theta_\infty(\omega)\), with

\[
\sin^2 \theta_\infty = \frac{\omega}{D} \left( 1 - \frac{1}{\omega^2} \right), \quad D = \frac{4\pi D}{(k + 1)} \omega_\text{pl}^\text{surf},
\]

where \(q = q(\cos \theta, \sin \theta)\), \(\omega_\text{pl} = \omega/\omega_\text{pl}^\text{surf}\), and \(\omega_\text{surf} = \omega_\text{pl} \sqrt{\kappa/(k + 1)}\). Equation (10) was obtained by taking the large \(|q|\) limit of Eq. (9). Since \(\sin^2 \theta_\infty / \cos \theta_\infty\) is even under \(\theta_\infty \rightarrow -\theta_\infty\), there are two asymptotes, see Fig. 2(a).

The FAP velocity on a given branch \(j\), and at a given wave vector \(q\), \(d\omega/\partial q\), is directed perpendicular to the corresponding constant frequency contour at \(q\) [Fig. 2(a), black arrows]. Due to their hyperbolic character, large wave vector FAPs at a given frequency in Eq. (10) all propagate along the specific direction \(v_\text{pl} = |\sin \theta_\infty| \hat{x} - \text{sgn}(\sin \theta_\infty) \cos \theta_\infty \hat{y}\), independent of \(q\) (for \(|q| \ll k\), where our treatment is valid). Consequently, these FAPs propagate as collimated beams. Further, as allowed by broken TRS, hyperbolic FAP modes are nonreciprocal: As shown in Fig. 2(a), the FAP velocity is \(\hat{s}\). Due to their hyperbolic character, large wave vector FAPs at a given frequency in Eq. (10) all propagate along the specific direction \(v_\text{pl} = |\sin \theta_\infty| \hat{x} - \text{sgn}(\sin \theta_\infty) \cos \theta_\infty \hat{y}\), independent of \(q\) (for \(|q| \ll k\), where our treatment is valid). Consequently, these FAPs propagate as collimated beams. Further, as allowed by broken TRS, hyperbolic FAP modes are nonreciprocal: As shown in Fig. 2(a), the FAP velocity is \(\hat{s}\). Indeed, the FAP velocity on a given branch and at a given wave vector is directed perpendicular to the corresponding constant frequency contour at \(q\).

The asymptotic pitch \(\theta_\infty\) of each hyperbolic constant frequency contour, and hence the direction \(v_\text{pl}\) of collimated FAP propagation, is controlled by the frequency \(\omega\), see Eq. (10). Approaching the conventional surface plasmon frequency \(\omega_\text{pl}^\text{surf}\) from above, the right-hand side of Eq. (10) approaches zero from below and the linear asymptotes bend towards \(\hat{x}: \theta_\infty \rightarrow \pm \pi \). Consequently, the FAP velocity \(v_\text{pl}\) cant towards \(\hat{y}\), the direction perpendicular to the chiral surface velocity \(v_\text{pl}^\parallel \hat{x}\), see Eq. (4). This behavior for \(\omega \gtrsim \omega_\text{pl}^\text{surf}\) results from the resonant hybridization of intra-Fermi arc oscillations with the conventional metallic surface plasmon mode.

A further striking signature of the coupled bulk and surface carrier dynamics of the WSM can be found in the FAP dispersion for \(q_x = 0\) [see Fig. 2(b)], where the Drude weight \(D\) drops out of Eq. (9). Analyzing the limits \(q_x \rightarrow 0^+\) in Eq. (9), we find a discontinuity in the FAP dispersion (within branch 1) between \(q_x \rightarrow 0^+\) and \(q_x \rightarrow 0^-\):

\[
\omega_\text{pl}^{(1)}(\omega) = \sqrt{2\pi/\sigma_H(1 + k)^2 + \omega_\text{pl}^\text{surf}^2} \pm 2\pi\sigma_H/(k + 1),
\]

where \(\omega_\text{pl}^{(1)}(\omega) = \omega_\text{pl}^{(1)}(q_x = 0^+, q_y = 0)\). A similar splitting also arises for branch 3. However, there is no splitting for branch 2 since \(\omega_\text{pl}^{(2)}(q_x = 0, q_y = 0) = 0\). For typical parameters (see Fig. 2 and Ref. [35]), we expect the splitting to be in the midinfrared.

The discontinuity in Eq. (11) arises from bulk anomalous Hall currents directed into or out of the surface. These currents are driven by the in-plane electric field associated with FAP waves \(e^{i\omega t - iq_x x}\) that propagate along \(+\hat{x}: q_x > 0\) or \(-\hat{x}: q_x < 0\), respectively [28,29,42]. We note that retardation effects [29] and finite sample thickness will smear the discontinuity at very small \(q_x\) [Fig. 2(b), gray region]. The splitting \(\omega_\text{pl}^{(1)}(\omega) - \omega_\text{pl}^{(1)}(\omega)\) is proportional to \(\sigma_H\) and thus provides the basis for a dynamical measurement of the anomalous Hall conductivity in WSMs. Interestingly, for small bulk densities, the role of these anomalous Hall currents becomes dominant, and the FAP frequency becomes insensitive to \(\omega_\text{pl}\): \(\omega_\text{pl}^{(1)}(\omega) \rightarrow 4\pi\sigma_H/(k + 1)\).

In addition to the hyperbolicity discussed above, FAPs with elliptic constant frequency contours also occur in small frequency windows near \(\pm \omega_\text{surf}^\text{surf}\), see yellow dashed lines in Fig. 2(a). Focusing on the case \(\omega > 0\) (branch 1), closed contours exist at frequency \(\omega\) if there is a finite, positive value of \(q\) that satisfies Eq. (9) for \(q_y = 0, q_x = 0\). This condition is realized for \(\omega_\text{pl}^{(1)}(\omega) < \omega < \omega_\text{pl}^\text{surf}\). Similar considerations hold for branch 3.

V. DISCUSSION

In this work, our aim has been to expose the unique phenomenology of surface plasmons arising from the coupled dynamics of bulk and topological surface states carriers in Weyl semimetals. The hyperbolic character of FAPs can be probed, e.g., via scanning near-field optical microscopy (SNOM) [43,44]. On the surface of a WSM, the near-field tip may launch a pair of collimated beams along the two directions of \(v_\text{pl}\) consistent with the applied excitation frequency; the propagation is biased along the direction of the chiral velocity, \(v_\text{pl}^\parallel \hat{x}\). In contrast, in hyperbolic materials with TRS, collimated plasmon beams are launched in fours [45,46], with reflection symmetry in \(x\) and \(y\).

Before closing, we briefly outline the material characteristics that favor FAP observation. For example, plasmon excitations with energies in the bulk interband particle-hole continuum are damped by electron-hole pair creation. Hence it is desirable to have a small surface plasmon frequency \(\omega_\text{pl}^\text{surf}\) (around which the FAP characteristics are most pronounced), which is below the interband threshold. Additionally, since \(\omega_\text{pl}^\text{surf}\) is directly determined by total carrier density, whereas the interband pair creation threshold is determined by the Fermi energy relative to the Weyl nodes, WSMs with low carrier densities, but with moderately high Fermi energy, are favored. In particular, these considerations seem to favor WSMs with only a few pairs of Weyl nodes [26].

The twin hyperbolic and chiral character of FAPs may yield new photonic tools such as an intrinsically nonreciprocal Purcell enhancement of spontaneous emission for emitters placed close to a WSM surface. Along with the prospects of using FAPs as dynamical probes of the peculiar features of WSMs, these opportunities make the search for optimal materials for realizing FAPs, and detailed material-specific modeling of FAP characteristics, important directions for future exploration.

APPENDIX

A. Vanishing bulk metallic contribution to surface velocity

In an ordinary metal with no topological surface states, an excess surface density \(n_S^\parallel(\omega)\) may accumulate when the metal is pushed out of equilibrium. This surface charge
layer may host a surface current density $e\mathbf{v}_s^M = \sigma_s^M (-\nabla \phi)$, where $\sigma_s^M$ is the surface conductivity associated with the bulk metallic carriers accumulated on the surface. Taking a simple Drude model for the longitudinal surface conductivity, we write $\sigma_s^M = n_s^M e^2/(mi\omega)$. Here $m$ is the effective mass of the carriers. Writing $n_s^M = n_s^M(0) + \delta n_s^M$ and noting that, in equilibrium, $n_s^M(0) = 0$, we find $\sigma_s^M \propto \delta n_s^M$. Similarly, because $\phi(\mathbf{r}, \omega) = e f U(\mathbf{r}, \mathbf{r'}) \delta n(\mathbf{r'}, \omega) d\mathbf{r'}$ is generated by the plasmon’s density inhomogeneity, it also depends directly on $\delta n$. [Here $U(\mathbf{r}, \mathbf{r'})$ is the Coulomb kernel.] As a result, the surface velocity $\mathbf{v}_s^M$ supported by bulk carriers accumulated at the surface goes as $(\delta n)^2$. Hence, to linear order in $\delta n$, the surface current $\mathbf{v}_s$, Eq. (4) of the main text, is supported solely by the Fermi arc surface state carriers.

B. Velocity density of topological surface states

1. Chiral velocity sign and bulk-edge correspondence

Here we resolve the sign of the chiral velocity $\mathbf{v}_s^o$, Eq. (4) of the main text, associated with the topological surface states. Consider a potential $V$ that confines WSM carriers to the region $z < 0$. This confining potential produces a force in the $-\hat{z}$ direction, so that $e(-\partial_z V) \propto -\hat{z}$. Next we note that besides confining the carriers, $V$ may also give rise to an anomalous Hall current $\sigma_{s,z} (-\partial_y V)$. Due to the bulk-edge correspondence, the undergap anomalous Hall currents and edge currents from topological surface states move in the same direction. As a result, the surface velocity density satisfies

$$\text{sgn}(\mathbf{v}_s^o) = \text{sgn}(-\sigma_{s,z}/e^2) = \text{sgn}(\sigma_{sH}). \quad (A1)$$

Why is there a minus sign in the middle expression? The confining electric field points towards $-(1/e)\hat{z}$, giving an electric current in the direction $\text{sgn}(-\sigma_{s,z}/e)\hat{X}$. Further, the velocity and electrical current are related by another factor of $e$, giving the factor of $1/e^2$. Hence the sign of $\mathbf{v}_s^o$ is independent of the sign of the carrier charge, $e$. In the last expression we used $\sigma_{sH} = \sigma_{s,z} = -\sigma_{s,z}$. Note that on the opposite surface the confining force would point in the $+\hat{z}$ direction, yielding an opposite sign for the chiral velocity on that surface: $\text{sgn}(\mathbf{v}_s^0,\text{opp}) = \text{sgn}(-\sigma_{sH})$.

2. Drude model for Fermi arc $\hat{y}$-direction velocity density

The topological surface states of the WSM are characterized by a chiral velocity, oriented in the $\hat{X}$ direction (i.e., the direction perpendicular to the $k$-space line connecting the bulk Weyl nodes). Additionally, for a generic topological surface state dispersion, a nonequilibrium Fermi arc carrier distribution may carry a velocity density in the $\hat{y}$ direction, parallel to the line connecting the bulk Weyl nodes. The precise features of these $y$ currents depend on the details of the topological surface state dispersion and the scattering mechanisms on the surface. However, we note that the carriers may move in both the $+\hat{y}$ and $-\hat{y}$ directions, and at equilibrium (for zero electric field), the velocity density in the $\hat{y}$ direction vanishes, $v_{s,y}^0 = 0$. Hence, we use a simple phenomenological Drude model to capture the $y$ currents induced by in-plane electric fields:

$$e\mathbf{v}_y^o = \sigma_{syy} E_y = \frac{D}{i\omega + y} E_y, \quad (A2)$$

where $E_y = -\partial_y \phi$ is the electric field in the $\hat{y}$ direction and $y$ is the transport scattering rate along the surface. In the collisionless limit, $\omega \gg y$, the conductivity reduces to $\sigma_{syy} \rightarrow D/i\omega$.

We note that, unlike the response to $y$ fields described above, the chiral surface states do not possess a Drude type response to $x$-directed electric fields. While the application of an electric field may impart momentum to the carriers along $\hat{x}$, the linear, chiral dispersion along $\hat{X}$ ensures that, to leading order (at fixed density), there is no change to the $x$ component of velocity density. However, as described in the main text, an $x$-directed electric field causes the topological surface state density to change due to impinging currents brought about via the bulk Hall conductivity. Thus the velocity density $\mathbf{v}_s$ on the surface responds to electric fields in the $\hat{X}$ and $\hat{y}$ directions very differently, as captured by Eq. (4) of the main text.

C. FAPs in WSMs with multiple Weyl node pairs

Fermi arcs also exist in WSMs with multiple bulk Weyl node pairs, labeled by an index $i = 1, 2, \ldots$. Extending the two-fluid model used in the main text, we can associate bulk and surface densities $n_{s,i}$ and $n_{s,i}^M$ with each (where $\chi = \{M, F\}$ labels the bulk free carrier and topological surface state contributions to the surface density, respectively). In the same limit $\omega \tau_{\text{surf}} \gg 1$ considered in the main text, the fields $n_{s,i}^M$ and $n_{s,i}^H$ obey distinct equations of motion, similar to Eq. (5). Surface plasmons arising from the collective dynamics of these carrier densities can be obtained in the same fashion as detailed in the main text, with all components coupled through the common electrical potential $\phi$. For simplicity, throughout this section we take $\kappa = 1$.

To illustrate this approach, we confine ourselves to a system with two pairs of Weyl nodes, $i = 1, 2$. We take all four Weyl nodes to be situated in the $k_x-k_y$ plane, at $\pm \mathbf{d}_i^\parallel$ (i.e., $\mathbf{d}_i^\parallel \cdot \hat{z} = 0$). Each pair of Weyl nodes contributes a bulk Hall conductivity $\sigma_{s,H,i}$ with sign (and orientation) consistent with that described in Eq. (A1); we will assume that the longitudinal conductivity $\sigma_{s,x,i}$ is the same for all Weyl nodes. Here $\sigma_{s,x,i}$ is the contribution to the total longitudinal conductivity coming from a single Weyl node pair, $i$. Finally, the associated Fermi arcs for each pair of Weyl nodes possess a surface particle current density given by

$$\mathbf{v}_{s,i,x}(\mathbf{r}_s) = \left[ v_{s,i,x}^0(n_{s,i}^F(\mathbf{r}_s)\hat{d}_s^i - \frac{D}{i\omega}(\hat{d}_s^i \cdot \nabla)\phi(\mathbf{r}_s)\right] \hat{d}_s^i. \quad (A3)$$

Here $\hat{d}_s^i$ and $\hat{d}_s^\parallel$ are unit vectors (in the $x-y$ plane) that describe the directions parallel and perpendicular to the vector connecting the $i$th pair of Weyl nodes, respectively, with $
abla^i = \hat{d}_s^i \times \hat{z}$. $D$ describes the Drude weight for a single Fermi arc, $i$.

Similar to Eq. (8) of the main text, the total accumulated surface density can be written in terms of the electric potential, $\partial_t n_i = \sum_{i,\hat{z}} G_i^\parallel \phi^\parallel$, with

$$G_i^\parallel = -\frac{q^2}{i\omega} \hat{d}_s^i \cdot \hat{d}_s^i \mathbf{G}_i^\parallel = \frac{\sigma_{M,i}^L(\hat{d}_s^i \cdot \mathbf{q} + \frac{D}{i\omega}(\hat{d}_s^i - \hat{d}_s^\parallel) \cdot \mathbf{q})^2}{(e(\omega - v_{s,i}^0,\hat{d}_s^i \cdot \mathbf{q})^2). \quad (A4)$$

The collective modes (surface plasmons) are found by seeking the combinations of $\omega$ and $\mathbf{q}$ such that the boundary conditions
of continuous $\phi_q$ and of the jump in the electric displacement field can be satisfied, as described above Eq. (9) in the main text. Thus we must solve the generalized secular equation

$$-2q + 4\pi e \sum_{i,x} G_i^x = 0. \quad (A5)$$

To derive the dispersion relation, analogous to Eq. (9), we first write $4\pi \tilde{\sigma}_{H,i}/k = \omega_{pl}^2/(2i\omega)$, where $\omega_{pl}$ is the bulk plasmon frequency of the WSM. Here, the factor of 2 in the denominator on the right-hand side reflects the fact that, in this example, the two Weyl node pairs each contribute half the total density of bulk free carriers. Collecting terms with factors $(\omega - v_{s,i}^0 \hat{d}_i^x \cdot \mathbf{q})$ and $(2 - \omega_{pl}^2/\omega^2)$, we obtain:

$$2(\omega - v_{s,1}^0 \hat{d}_1^x \cdot \mathbf{q})(\omega - v_{s,2}^0 \hat{d}_2^x \cdot \mathbf{q}) \left[ 1 - \frac{(\omega_{pl}^2)^2}{\omega^2} \right] + M_1 + M_2 = 0, \quad (A6)$$

where $\omega_{pl}^2 = \omega_{pl}/\sqrt{2}$ (taking $\kappa = 1$), and the hybridization amplitudes are given by

$$M_1 = (\omega - v_{s,1}^0 \hat{d}_1^x \cdot \mathbf{q}) \left[ -4\pi \sigma_{H,1}(\hat{q} \cdot \hat{d}_1^x) - \frac{4\pi D_0|\mathbf{q}|}{\omega}(\hat{q} \cdot \hat{d}_1^x)^2 \right],$$

$$M_2 = (\omega - v_{s,2}^0 \hat{d}_2^x \cdot \mathbf{q}) \left[ -4\pi \sigma_{H,2}(\hat{q} \cdot \hat{d}_2^x) - \frac{4\pi D_0|\mathbf{q}|}{\omega}(\hat{q} \cdot \hat{d}_2^x)^2 \right]. \quad (A7)$$

We note that for nonvanishing $M_{1,2}$, the collective oscillations in the chiral branches $(\omega - v_{s,i}^0 \hat{d}_i^x \cdot \mathbf{q}) = 0$ and the conventional surface plasmon mode described by $[1 - (\omega_{pl}^2)^2/\omega^2] = 0$ will hybridize, giving rise to FAPs. The structure of the resulting plasmon bands will depend on the magnitudes of the hybridization amplitudes, as well as the positions and orientations of the pairs of Weyl nodes (as encoded in the $\{\hat{d}_i\}$).

Seeking hyperbolicity, we note that, at large $q$, the terms going as $O(q^2)$ dominate Eq. (A6). Using this large $q$ limit, we determine the asymptotic contours via:

$$2(v_{s,1}^0 \hat{d}_1^x \cdot \mathbf{q})(v_{s,2}^0 \hat{d}_2^x \cdot \mathbf{q}) \left[ 1 - \frac{(\omega_{pl}^2)^2}{\omega^2} \right] = -\frac{4\pi D_0|\mathbf{q}|}{\omega} \left[ v_{s,1}^0 \hat{d}_1^x \cdot \mathbf{q}(\hat{q} \cdot \hat{d}_1^x)^2 + v_{s,2}^0 \hat{d}_2^x \cdot \mathbf{q}(\hat{q} \cdot \hat{d}_2^x)^2 \right]. \quad (A8)$$

As a sanity check, we note that for a WSM with two pairs of Weyl nodes that point in the same direction, $\hat{d}_1 = \hat{d}_2$ [and $v_{s,1}^0 = v_{s,2}^0 = v_0$], Eq. (A8) yields the same hyperbolae as described in the main text (setting $\kappa = 1$ and recalling $D_0 = D/2$).

We now illustrate the contours of FAPs in a situation with multiple (2) pairs of Weyl nodes, with $\hat{d}_1$ and $\hat{d}_2$ pointing in different directions. For demonstration, we take a simple model with $\hat{d}_1^x = \hat{x}$ and $\hat{d}_2^x = \hat{y}$:

$$\hat{d}_1 = \hat{x}, \quad \hat{d}_2 = \hat{y},$$

$$v_{s,1}^0 = v_{s,2}^0 = v.$$ Substituting the relations in Eq. (A9) into Eq. (A8), we find open constant frequency contours that asymptotically approach the lines $\theta = \theta_{\infty}(\tilde{\omega})$ at large $q$, with

$$\cos^3\theta_{\infty} - \sin^3\theta_{\infty} = \frac{\tilde{\omega}}{D_0} \left[ 1 - \frac{1}{\omega^2} \right], \quad (A10)$$

where $\tilde{\omega} = \omega/\omega_{pl}^2$. Here $D_0 = 2\pi D_0/(v_0 \omega_{pl}^2)$, as in the main text (with $\kappa = 1$). A complex pattern of asymptotic contour lines $\theta = \theta_{\infty}(\tilde{\omega})$ arises from the hybridization of ordinary surface plasmons modes with collective oscillations in the Fermi arc surface states and from hybridization between the collective modes of each of the separate branches of Fermi arc surface states (associated with the Weyl node pairs $i = 1, 2$).

D. Parameter estimates for $D$ and $\tilde{\sigma}_H$

In order to illustrate the properties of Fermi arc plasmons, we have used parameters $\tilde{\sigma}_H = 2.0$, and $D = 6.0$ in the figures of the main text. We emphasize that the qualitative features of FAPs do not depend on the specific values chosen. Experiments probing TRS breaking Weyl semimetal candidates have been intensifying. As a result, instead of concentrating on a single candidate compound, we have estimated physically reasonable parameter values ranges for $D$ and $\tilde{\sigma}_H$, which we discuss below.

In arriving at these ball-park values we have used the background dielectric constant $\kappa \sim 10$ as reported in Ref. [20] for the candidate Weyl semimetal Eu$_2$Ir$_2$O$_7$; we note that other Weyl semimetal candidates are also expected to have high background dielectric constants. Next, we noted that $\sigma_H = e^2/(2k_\pi h)$ (see main text) with the inter-Weyl node separation taking values that range approximately $2k_\pi \sim 0.02 - 0.1$ a. [5,6]. We also adopted a simple Drude model for $D \sim \tilde{n}e^2/m$ to capture the response of the topological surface state carriers to in-plane electric fields, in the general case where the Fermi arc is curved (see Sec.B). Here $\tilde{n}$ is a typical surface density between the Weyl nodes. In our subsequent estimate we have also obtained the effective collective mass of the electrons using $m \sim E_F/v^2$, with $E_F$ the Fermi energy.

Taking $\hbar \omega_{pl}^2 \sim 20 - 60$ meV [20], a typical $v$ on the surface $\tilde{v} \sim 10^8$ cm s$^{-1}$, and $E_F \sim 100$ meV, we arrive at order of magnitude estimates of $\tilde{\sigma}_H \sim 1 - 10$, and $D \sim 5 - 50$.  

205443-6

[35] See the Appendix for a discussion of Weyl semimetals with multiple pairs of Weyl nodes, vanishing bulk metallic contribution to surface velocity $\mathbf{v}^0$, and surface velocity density in the topological surface states, and typical parameter values for $\sigma_H$ and $\tilde{D}$ in a WSM.

[39] We estimate finite-\( q \) corrections to \( \sigma_H \) for \( k_y \) slices far from the Weyl nodes go as \( O[(\hbar v q / \Delta)^2] \), where \( v \) is the bulk Weyl velocity, and \( 2\Delta \) is the gap size in \( \varepsilon(k_x,k_z;k_y) \) for fixed \( k_y \). As a result, for \( q \ll \Delta / (\hbar v) \sim k_y \), \( \sigma_H \) per \( k_y \) slice far away from the Weyl nodes is approximately \( q \)-independent.

[40] We neglect the role of incidental, trivial surface states; even if they are present, they do not give rise to the peculiar FAP phenomenology that we unveil.
