(Received 10 August 2006; revised manuscript received 13 October 2006; published 11 December 2006)

We report a first-principles study on the geometric, electronic, and magnetic properties of V-doped anatase TiO$_2$. The DFT $+ U$ (Hubbard coefficient) approach predicts semiconductor band structures for Ti$_{1-x}$V$_{x}$O$_2$ ($x=0.625\%$ and 12.5%), in good agreement with the poor conductivity of samples, while the standard calculation within generalized gradient approximation fails. Theoretical results show that V atoms tend to stay close and result in strong ferromagnetism through superexchange interactions. Oxygen vacancy induced magnetic polaron could produce long-range ferromagnetic interaction between largely separated magnetic impurities. The experimentally observed ferromagnetism in V-doped anatase TiO$_2$ at room temperature may originate from a combination of short-range superexchange coupling and long-range bound magnetic polaron percolation.

DOI: 10.1103/PhysRevB.74.233201 PACS number(s): 75.50.Pp, 61.72.Ww, 61.72.Ji

The discovery of ferromagnetism (FM) in Co-containing TiO$_2$ semiconductors has attracted significant attention because of its potential application for developing functional devices that manipulate both spin and charge. However, the origin of FM observed in Co-doped anatase TiO$_2$ at and above room temperature is still under debate. Many experiments argued the intrinsic nature of FM, while the presence of the Co clusters in the samples could not be completely excluded. To study the observed FM, theoretical efforts have been made through analyzing the electronic and magnetic structures for various Co configurations in the host matrix. Yang et al. have pointed out that ferromagnetic ordering occurs only when Co atoms locate close to each other. One-plane-wave pseudopotential calculation supports that the short-range exchange between adjacent Co atoms could contribute to FM. In addition, oxygen vacancy is thought to play a key role in enhancing the FM coupling. Recently, V-doped anatase TiO$_2$ has been discovered to have a surprisingly high Curie temperature ($T_C > 400$ K). In contrast to Co-doped TiO$_2$ that has been widely studied theoretically, few investigations on V-doped TiO$_2$ have been reported in the literature. One interesting work by Wang et al. using LDA and LDA+$U$ methods investigates the electronic structure of Ti$_{15-x}$V$_x$O$_{32}$ ($x=0.625\%$) and argues that the neighboring V-V cations prefer FM at a high doping concentration ($x=0.25\%$) by employing a $2 \times 1 \times 1$ supercell. However, the relative stability among magnetic phases is extremely sensitive to atomic structure, its associated defects’ distribution, and dopant concentration, further investigation is desirable to gain better understanding of high $T_C$ FM in this system.

In this Brief Report, we use ab initio band-structure and total energy methods, implemented in the Vienna Ab initio Simulation Package (VASP), to study the geometric, electronic, and magnetic properties of V-doped anatase TiO$_2$ (Ti$_{1-x}$V$_x$O$_2$), in particular the effects of doping concentration ($x=0.625\%$ and 12.5%) as well as oxygen vacancy. The projector augmented wave (PAW) method is chosen to represent the electron-ion interaction. Exchange correlation interactions are described by the Perdew-Burke-Ernzerhof generalized gradient approximation (GGA). The Brillouin-zone (BZ) integration is performed on a well-converged Monkhost-Pack $k$-points grid. The plane wave kinetic energy cutoff is set to be 400 eV. Atomic positions and lattice parameters are optimized at the GGA level until the atomic forces are smaller than 0.01 eV/Å. To account for the strongly correlated interactions of the V 3$d$ electrons, a moderate on-site Coulomb repulsion ($U=3.0$ eV) has been applied only to V 3$d$ orbitals since further correction for the host material has little impact on the magnetic ordering.

We start with a Ti$_{15}$V$_{0.25}$O$_{32}$ supercell to model the low doping concentration case (6.25%), which is demonstrated in Fig. 1 and one V atom substitutes Ti at the Ti$_1$ site. The lattice parameters of optimized Ti$_{15}$V$_{0.25}$O$_{32}$ supercell are $a=7.64$ Å and $c=9.65$ Å, which are slightly smaller than those of perfect TiO$_2$ (our theoretical lattice parameters of Ti$_{15}$O$_{32}$ are $a=7.65$ Å and $c=9.68$ Å at the GGA level). Clearly, this type of substitution only leads to a small geometrical distortion in the vicinity of V impurity (less than 0.1 Å). To discuss the solubility of V in an anatase TiO$_2$ host, it is useful to define the substitution energy of V impurity as $E_s=E(Ti_{15}O_{32})+E(Ti)-E(V)-E(Ti_{15}O_{32})$, where $E(Ti_{15}O_{32})$, $E(Ti)$, and $E(V)$ are the total energy of a $2 \times 2 \times 1$ supercell of pure anatase TiO$_2$, the bulk hcp Ti, and bcc V, respectively. $E_s$ is predicted to be 2.34 eV, which is even less than one-third of the substitution energy of Co dopant (8.51 eV). This result agrees nicely with experimental observation that V impurity is well-dissolved into TiO$_2$.

The band structure, total density of states (DOS), and V 3$d$ partial DOS (PDOS) of Ti$_{15}$V$_{0.25}$O$_{32}$ are presented in Fig. 2. The calculation at GGA level suggests that the DOS near the Fermi surface ($E_F$) mainly originates from V 3$d$ orbitals, which is shown in Fig. 2(c) for clarity. The V impurity band has strong anisotropic character in the a-b plane (i.e., $A \rightarrow R$ and $\Gamma \rightarrow M$), however, it is less dispersive along the $c$ axis of the BZ (i.e., $M \rightarrow A$ and $Z \rightarrow \Gamma$). It is important to note that $E_F$ is largely crossed by spin-up states, while spin-down
states only cut $E_F$ slightly. This indicates that the system is nearly half-metallic at the GGA level. As there exists strongly correlated interaction in V 3$d$ shells, we choose DFT+$U$ as a scheme beyond-GGA level. The calculated PDOS by DFT+$U$ are plotted in Figs. 2(e) and 2(f). We find that the metal-insulator-transition occurs when the parameter $U$ is applied to the V atom. This strong correlation lifts the degeneracy of $t_{2g}$ states, so as to open the gap. An occupied band composed of mainly $d_{xy}$ component is split off from the bottom of the conduction band. These features suggest that Hubbard $U$ correction increases the localization of the V $d$ electrons. Results presented above are fundamentally consistent with Ref. 14 except for their lifted Ti PDOS due to additional corrections for Ti 3$d$ states.

It can be expected that the direct impurity interaction cannot yield experimentally observed strong FM because of the large V-V distance. The original supercell is extended along the $b$ and $c$ axes to form $2 \times 4 \times 1$ and $2 \times 2 \times 2$ supercells (Ti$_{30}$V$_2$O$_{64}$) to examine magnetic ordering. From Table I, the calculated energy difference between the AFM and FM states ($\Delta E$) is negative, which indicates that the ground state is AFM for both cases as expected. Moreover, the on-site Coulomb repulsion at V atom strengthens AFM with a small increase of magnetic moment. The AFM ground state is further confirmed by our calculation using the hybrid B3LYP functional as implemented in CRYSTAL03 code. To understand the experimental observed high $T_c$ in V-doped TiO$_2$, one has to search other origins to lead FM. In the rest of this Brief Report, first we explore the effects of closely distributed V impurities especially at high doping level, then oxygen vacancy on electronic and magnetic properties.

According to Janisch et al.’s suggestion, we have constructed three Ti$_{14}$V$_2$O$_{32}$ structures to model high impurity concentration (12.5%) V-TiO$_2$, where a second V atom occupies the Ti$_2$, Ti$_3$, or Ti$_4$ site in the Ti$_{15}$V$_2$O$_{32}$ supercell, named the chain, grid, and nearest-neighbor (NN) configurations (the optimized V-V distance is 3.82, 5.39, and 3.06 Å), respectively. From Table I, $\Delta E$ is positive for all three cases within the GGA approach and increases with V-V distance decreasing. We find that the energy of the NN configuration is the lowest, strongly favoring V-dopants clustering.

The DOS shapes have almost the same characteristic shapes among three configurations, hence, only the ones for the nearest-neighbor configuration is presented in Fig. 3. Similar to the Co-TiO$_2$ case, when $x$ increases from 6.25% to 12.5%, the total DOS, V 3$d$ PDOS, and magnetic moment of V cation change slightly. The DOS and PDOS by DFT+$U$ are presented in Figs. 3(b) and 3(d), which reveal that the system becomes a semiconductor when the parameter $U$ is applied. It is consistent with the poor conductivity observed in V-TiO$_2$ samples. The on-site $U$ correction shifts the $d_{xy}$ state down to the middle gap, while at the GGA level it is a mixture of three $t_{2g}$ orbitals ($d_{xz}$, $d_{yz}$, and $d_{xy}$) locating at $E_F$.

The larger separation between the occupied and empty V 3$d$ states, due to strong correlation, results in the decrease of the $\Delta E$ value and even the change of its sign for the chain and grid configurations in Table I. The remarkable observation in our work is the high fidelity of $\Delta E$ for the NN configuration. As it is extremely hard to choose the accurate value for $U$, this result is particularly valuable to highlight the important contribution of the V-O-V NN configuration to yield a FM state.

The reason for the weakened FM couplings within DFT+$U$ could be sought in terms of the $p$-$d$ hopping mechanism. The V impurities interact with orbitals of the same symmetry and form a set of bonding-antibonding states. Within GGA approximation, the FM state has an energy gain through the partial occupancy of V $t_{2g}$ states. The Hubbard $U$ at V sites results in a fully occupied $d_{xy}$ band. In a FM arrangement, both bonding and antibonding levels are filled, and there is no energy gain for this coupling.

TABLE I. Calculated energy difference between the AFM and FM states [$\Delta E=E(\text{AFM})−E(\text{FM})$], and the ground state magnetic moment ($M$) per V atom for various configurations at the GGA level and at the DFT+$U$ level. The data inside the parentheses are obtained by the DFT+$U$ approach.

AFM arrangement, the bonding states are filled for both spin up and down channels, while the antibonding ones are empty. It implies that AFM is favored between adjacent V cations when correlation effect is taken into account. However, there exists a strong competition due to superexchange. It is well-known that superexchange may have a FM contribution for filled shells. Recently, Janisch et al. argued that short-range superexchange between a 90° metal-anion-metal bond plays a significant role in transition metal doped anatase TiO₂. We believe the FM originates from the superexchange interaction with the V–O–V bond angle about 104.9° in the NN configuration.

As indicated by previous work, the presence of oxygen vacancy (V₀) may influence the distribution of dopants. To study the impact of V₀, three cases are considered: (a) Ti₁₅O₃₂ with one oxygen atom removing from the 2×2×1 supercell of TiO₂; (b) the basal oxygen (O₁) of V-contained octahedron is removed from Ti₁₅VO₃₂ and subsequently the oxygen deficient cell is doubly enlarged along the b axis, named as the basal O₁ 2×4×1 configuration; and (c) V₀ occupies the vertex site of V-incorporated octahedron (by removing O₂) and the original supercell is doubly extended along the c axis, denoted as the vertex O₂ 2×2×2 configuration. After removing an oxygen atom from the cation-contained octahedron, the original structure experiences a considerable distortion. Cations next to the V₀ site are repelled away. The calculated total energies indicate that V₀ prefers to stay close to V than near Ti.

Figure 4 shows the DOS results for the Ti₁₅O₃₂ and basal O₁ 2×4×1 configurations. When an oxygen atom is removed, a nonmagnetic defect state (mainly from Ti cations near V₀) appears at the bottom of the conduction band. If a V atom occupies the cation site of the oxygen-deficient octahedron, V 3d states overlap in energy with the defect state which yields 0.11 e transferred from the defect state to the empty V 3d spin-up state enhancing spin polarization of the
FIG. 4. (Color online) DOS structure of oxygen deficient Ti_{16}O_{31} and the basal O_{2} 2\times4\times1 configuration (Ti_{16}V_{2}O_{31}). The vertical line denotes the Fermi level.

V ion. It fits quite well with the physical picture proposed by Coey et al. that the hybridization between the defect state and magnetic dopants’ states will promote FM. However, the V_{O} mediated magnetic coupling is sensitive to distance. The polarons induced by V_{O} tend to parallelize their spins, corresponding to a ferromagnetic arrangement, only when their distance is less than a critical value, which is the case in the basal O_{2} 2\times4\times1 configuration. When their distance increases larger than this critical value, the strict spin alignment between polarons disappeared. This leads to a loss of long-range coherence, as in the vertex O_{2} 2\times2\times2 case. Further efforts are needed to determine the exact critical distance required for polaron percolation in this system. DFT+U calculations qualitatively do not change the result given by GGA.

In summary, we have studied the structural, electronic, and magnetic properties of V-doped anatase TiO_{2} by both GGA and DFT+U calculations. The correlation effect is not well-represented by GGA, while DFT+U calculations give a better physical picture. The results suggest that direct exchange between well-separated V ions cannot account for the observed FM in this system. The superexchange interaction is responsible for the stable FM between nearest-neighbor V cations. The long-range interactions between oxygen defects induced magnetic polarons are sensitive to their distance. Provided that macroscopic ferromagnetic clusters appear by polarons overlapping, the system favors FM. Thus a combination of the long-range polaron percolation and the short-range superexchange through nearest-neighbor V atoms could contribute to the high T_{C} FM in V-doped anatase TiO_{2}.

We thank Y. Wang for a helpful discussion. This work was partially supported by the National Natural Science Foundation of China under Grant Nos. 20303015, 10674121, 50121202, and 20533030, by the USTC-HP HPC project, and by the SCCAS and Shanghai Supercomputer Center.
