A circular ferrofluid driven microchip for rapid polymerase chain reaction

Y. Sun\textsuperscript{a}, Y. C. Kwok\textsuperscript{a} and N. T. Nguyen\textsuperscript{a,b}

\textbf{Introduction}

The Polymerase chain reaction (PCR) process is widely used as a molecular biological tool to replicate DNA, and can create copies of specific fragments of DNA by cycling through three temperature steps. Each temperature cycle can double the amount of DNA, and 20–35 cycles can produce millions of DNA copies. Recently, much attention has been paid to the development of miniaturized PCR devices\textsuperscript{1,2}. All kinds of PCR microfluidic technologies have facilitated DNA amplification with much faster rates as a result of smaller thermal capacity and larger heat transfer rate between the PCR sample and temperature-controlled components\textsuperscript{3}. Two basic types of PCR devices have been described, namely temporal PCR devices and spatial PCR devices\textsuperscript{4}. In a temporal PCR device, the sample solution is introduced into a small chamber. Thermal cycling is realized by heating and cooling the reaction chamber repeatedly according to required temperatures of the denaturing, annealing and extension processes. Such small chambers are difficult and expensive to fabricate, the temperature control system is usually bulky and the heating and cooling rates are relatively low\textsuperscript{5}.

For spatial PCR devices, the PCR reaction mixture, instead of being held in a thermal cycling chamber, is pumped into a serpentine microfluidic channel and passes repeatedly through three spatially fixed temperature zones. In this concept, temperature at a specific location only needs to be controlled at a constant value. The first spatial PCR device was developed by Kopp \textit{et al}\textsuperscript{6} and called continuous-flow (CF) PCR device. Since then, a number of CFPCR systems based on both glass and polymer have been introduced. Currently, most researchers use syringe pump\textsuperscript{7,8}, peristaltic pump\textsuperscript{9} or rotary pump\textsuperscript{10} to control the flow of PCR solution through microchannels. Although successful DNA amplification has been reported for many CFPCR devices, some problems may ultimately hinder their widespread use. Significant limitations of CFPCR devices include the large footprint of microchip due to the long serpentine microchannel required for multiple PCR cycles and the fixed cycle number which is dictated by the channel layout. Moreover, the use of various pumps imposes high requirement on microchip bonding integrity. Liquid leakage has frequently been observed due to the large pressure involved. In addition, bonded cost and bulky size of pumps make it difficult to realize true micro total analysis systems (\textmu TAS).

One solution for the long microchannel of CFPCR devices is containing the flow in a closed loop. Krishnan \textit{et al}\textsuperscript{13} used temperature gradients in a 35-\textmu L cylindrical cavity for both driving and thermal cycling of the PCR mixture. The mixture circulates vertically between 97°C and 61°C due to natural convection. This concept was further extended to close-loop designs with rectangular shape\textsuperscript{14}, triangular shape\textsuperscript{15} and semicircular shape\textsuperscript{16}. The major drawback of this concept is that the driven force based on natural convection is a body force, which is proportional to the volume and does not scale favourably in microscale. Consequently, the concept only works with devices in mesoscale with channel size on the order of millimeters.

Magnetic force can be used to drive the PCR mixture in a close-loop channel. Although magnetic force is also a body force, this actuation concept can be miniaturized due to the possible high magnetic field gradient in microscale. Hatch \textit{et al}\textsuperscript{17} previously reported a micropump using a ferrofluid plug as a piston, which is driven by an external magnet. Similar magnetic actuation was also reported later by Yamahata \textit{et al}\textsuperscript{18}. Both of the devices were used for continuous pumping of liquids.

In this paper, we present a close-loop circular ferrofluid driven microchip for rapid PCR. An external magnet is used to drive a small ferrofluidic plug inside the circular microchannel, which in...
The number of thermal cycles can be varied by controlling the number of rotation cycles of the magnet. Cycle time of the PCR mixture is adjusted by changing the rotation speed of the magnet. Effects of cycle number and cycle time on PCR products were investigated. The microchip has much simpler design and smaller footprint compared to the rectangular serpentine CFPCR devices, and using magnet as the driving force provides the advantages of low cost, small power consumption, low requirement on microchip bonding integrity and flexible number of PCR cycles. Forensic application was demonstrated by performing amplification of 16-loci short tandem repeat (STR) sample on the PCR microchip.

Concept of ferrofluid driven method

A ferrofluid is a stable colloidal suspension of sub-domain magnetic particles in a liquid carrier. Each ferro-particle has an average size of about 100 Å (10 nm). These ferro-particles are specially coated with surfactant, a stabilizing dispersing agent to prevent agglomeration due to strong magnetic field gradient applied to the ferrofluid, as well as to maintain the colloidal and thermal stabilities, which are crucial to PCR applications. The ferrofluid used in our experiment contains 5% magnetic solid, 10% surfactant and 85% carrier by volume. The carrier liquid is synthetic ester oil, which is immiscible with the aqueous PCR mixture and a cycle time from 46 sec to 8 sec. The full PCR cycle was completed when the magnet turned one round. The speed of the magnet can vary from 1.3 to 7.5 rpm, corresponding to a linear velocity from 1.4 to 7 mm/s for PCR reaction mixture and a cycle time from 46 sec to 8 sec. The number of PCR cycles can be chosen arbitrarily by programming the rotation cycles of the magnet.

Microfabrication

The design of the microchip was much simpler compared to the rectangular serpentine CFPCR devices. It consists of a deep close-loop circular channel for PCR reaction and two shallow straight channels tangent to the circle for sample injection and collection. The PCR chip was fabricated in polymethyl methacrylate (PMMA) substrate by laser ablation. The microfluidic pattern was designed using CorelDraw (Corel Co., Canada). The pattern was then sent to a commercial CO2 laser scriber (Universal M-300 Laser Platform, Universal Laser Systems Inc., Arizona, USA) for direct micromachining on PMMA substrate. Inspection of scanning electron micrographs (SEM) indicated that the channel had a Gaussian-shaped cross section due to the Gaussian distribution of the laser beam energy. Access holes were also drilled by the same CO2 laser to allow fluid access to the microchannels. To form the microfluidic device, the engraved substrate was then bonded together with a cover plate by a low pressure, high temperature thermal bonding technique under pressure of 20 kPa at 165 °C for 30 minutes.

As shown in Fig. 2, the outer dimension of the chip was 30 mm × 30 mm. The circular channel was 62.8 mm long (with a diameter of 20 mm), 200 µm wide and 250 µm deep, and each temperature zone was 21 mm long. The total volume was 2 µl, about one to two orders smaller than that of devices based on natural convection reported before. Two shallow straight channels were 10 mm long, 100 µm wide and 50 µm deep to reduce sample waste. Rectangular holes labelled as “thermal gaps”, were machined in a radial fashion to ensure proper heat isolation between different temperature zones. Small circular holes were drilled 200 µm away from the microchannel as sensing ports for measuring the temperatures around the loop. Access to the microchannel was provided by Teflon tubing attached to two holes drilled into the cover substrate.
Preparation of PCR mixture

To test the fidelity of the PCR microchip, a 500 bp fragment of bacteriophage lambda DNA was amplified. Forward primer was 23-mer (5’-GAT GTC GTG TCC GTA CAA CT-3’) with a melting point of 64.1 °C. The primer coordinates are 7131-7155 on the lambda DNA template. Reverse primer was 23-mer (5’-GGT TAT CAG AAT CAG CCA CAG CGT-3’) with a melting point of 70.3 °C. The primer coordinates are 7608-7630 on the template. The reaction mixture contained 10 mM Tris-HCl (pH 8.3), 2 x BSA (0.5 µg/µL), 50 mM KCl, 1.5 mM MgCl₂, 200 µM of each dNTP, 1 µM of each primer, 1 ng/µL lambda DNA as the PCR template, and 0.025 U/µL Taq DNA polymerase. All samples and reagents for PCR reaction were purchased from Research Biolabs (Singapore). The ferrofluid (APG S10n) used in the experiment was purchased from Ferrotec (CA, USA).

One important application of the ferrofluid driven PCR microchip is to amplify forensic DNA. DNA fingerprinting requires the co-amplification of sixteen loci, fifteen STR loci and Amelogenin. STRs are short repeated sequences appeared in human genes at different chromosomes. The ferrofluid driven PCR microchip were tested using Applied Biosystems Identifiler® STR analysis kit (Applied Biosystems, Foster City, CA, US) with 0.04 ng/µl 9947 female DNA template (Promega, Madison, WI, USA). Amplicon allele size ranges between 100 to 360 base pairs. Four fluorescent dyes (6-FAM, VIC, NED, and PET dyes) were used to label DNA fragments. All STR loci included in the Applied Biosystems Identifiler® STR analysis kit co-amplified in a single PCR.

Procedure

As shown in Fig. 3, the temperature of the denaturation zone was set at 95 °C, annealing zone at 60 °C and extension zone at 72 °C. Temperatures inside the microchannel were measured using a K-type thermocouple (Tri-X Pte Ltd, Singapore).

The microchip was placed on top of the heating blocks. For amplification, following a 2-min flush with deionized (DI) water, the PCR mixture was injected using a glass syringe (Hamilton, NV, USA) through Teflon tube (Cole Parmer, Illinois, USA) fitted to the chip inlet hole. After the channel was completely filled, a small portion (0.5 µl) of ferrofluid was injected through the same inlet port. The inlet and outlet ports were then sealed with epoxy gel (3M, Minnesota, USA).

Upon introduction of magnetic field, the ferrofluid plug immediately moved with the rotating magnet. PCR reaction mixture was pushed around the circular channel and flowed through the three temperature zones continuously. The cycle time of PCR reaction mixture was changed by adjusting the rotational speed of the magnet and the number of PCR cycles was varied by selecting the number of rotation cycles of the magnet. After amplification, the epoxy gel was removed and the PCR products were propelled by a syringe and collected into a polypropylene tube at the outlet. Subsequent to each run, the microchip was washed by DI water and negative control of PCR was done to make sure that there was no carryover. The simplicity of the system should make it possible to use the chip as a disposable, thus the washing step is not necessary.

Effect of cycle number

To demonstrate that PCR can be achieved by the magnetically driven concept, amplification of 500 bp lambda DNA fragment was conducted on the PCR microchip. The effect of cycle number was studied. This was achieved by varying the number of rotation of the magnet. The rotation speed of the magnet was selected to be 2.2 rpm, giving a cycle time of 27 s, i.e. 9 s at each temperature zone. It would take two hours to finish a 30-cycle PCR on a conventional thermal cycler, while it only took 13.5 min to finish the amplification on microchip.
amplification efficiency for larger DNA fragment can be further increased by adding a pre-denaturation reactor at the inlet and a post-extension reactor at the outlet.

**Amplification of 16-loci STR sample**

A volume of 1.5 μl PCR reaction mixture and 0.5 μl ferrofluid were injected through inlet. 25 cycles of amplification was completed in 13 mins with flow velocity of 2 mm/s and cycle rate of 31.4 sec/cycle. The time was greatly reduced compared to almost 2 hours when using conventional thermal cycler. Triplicate amplification was carried out and negative controls were conducted in between template-containing runs.

Electropherograms for 9947 female DNA and negative control are shown in the Electronic Supplementary Information. For 9947, all 16 allele were successfully amplified. Although relative fluorescence units (RFUs) were mostly under 100, which were relatively lower than those achieved from conventional thermal cyclers, peak heights were very balanced and no obvious imbalanced peak was observed. The low RFUs can be overcome by increasing amplification cycles. RFUs of negative control were all under 10, proving that there was no carryover and cross contamination.

**Conclusions**

In this paper, a novel circular ferrofluid driven PCR microchip has been developed and successfully demonstrated by performing PCR amplification of a 500 bp lambda DNA fragment and a 16-loci forensic DNA sample. The intensity of PCR product increases exponentially with the number of cycles until a saturation point. As the thermal cycle number in the PCR microchip was adjustable by controlling the magnet rotation cycles, an optimum cycle number could be chosen for different DNA concentrations. The cycle time of the PCR mixture was controlled by the rotation speed of the external magnet. The microchip has much simpler design and smaller footprint compared to the rectangular serpentine CFPCR devices, and this simple method to carry out PCR thermal cycling using ferrofluids in a close-loop microchannel potentially offers a big step toward a real micro TAS for its small power consumption, ease of operation and low cost. It is expected that the presented device concept could be widely used in forensic, clinical and biotechnological applications. The problem of low sample throughput can be tackled by designing a series of concentric circles on one microchip. As the dimension of microchannel is small compared to the external magnet, one magnet is adequate to drive PCR reaction mixture in all the microchannels. The freedom of choosing different times for the three temperature zones could be realised by changing the geometry of microchip layout. Other than annular loop, triangular shape is another option. By designing different lengths at three temperature zone, different cycling time is achievable. The pre-denaturation and post-extension on chip is also possible by adding two reactors at the inlet and outlet. We have recently developed a rotate-and-slide mechanism that allows the external magnet to move along an arbitrary closed path, which can replace the current simple circular path. These are the future directions of our research.

In the future, we will devote to the development of parallel ferrofluid driven PCR microchip and the integration of PCR microchip with capillary electrophoresis (CE) microchip.
