(Received 16 December 2011; revised manuscript received 7 February 2012; published 6 April 2012)

We present a theory for the time-resolved optical spectroscopy of high-temperature superconductors at high excitation densities with strongly anisotropic electron-phonon coupling. A signature of the strong coupling between the out-of-plane, out-of-phase O-buckling mode \(B_{1g}\) and electronic states near the antinode is observed as a higher-energy peak in the time-resolved optical conductivity and Raman spectra, while no evidence of strong coupling between the in-plane Cu-O-breathing mode and nodal electronic states is observed. More interestingly, it is observed that under appropriate conditions of pump fluence, this signature exhibits a reentrant behavior with time delay, following the fate of the superconducting condensate.

I. INTRODUCTION

Since its discovery in 1986, high-temperature superconductivity in cuprates has been a central topic of study in condensed-matter physics. It is now widely believed that Cooper-pair formation is essential for the superconducting condensate in these systems. However, the nature of the mediator (or glue) responsible for Cooper pairing remains hotly debated. Although the interaction of electrons with lattice vibrations is not likely to solely account for the essential properties of high-\(T_c\) superconductors (HTSCs), many probes, including angle-resolved photoemission,\(^1\) inelastic neutron scattering,\(^6\) tunneling,\(^7,8\) and Raman\(^9\) spectroscopies, have revealed that electron-phonon interactions have significant effects on various properties. Complementary to the time-integrated techniques, different ultrafast pump-probe techniques\(^10\) have been used to disentangle microscopic interactions in HTSCs. These techniques aim to study the recombination of photoexcited quasiparticles and the resulting recovery of the superconducting condensate. In HTSCs, time-resolved (TR) angle-resolved photoemission spectroscopy\(^16\) and TR optical reflectivity\(^17\) have indicated that the excited quasiparticles preferentially couple to a small number of phonon subsets before decaying through anharmonic coupling to all other lattice vibrations in support of the notion that selective optical-phonon modes give rise to anisotropy of the electron-phonon (el-ph) coupling.\(^5\) In addition, this anisotropy has also been observed in TR electron diffraction,\(^18\) while the resonant femtosecond study of both electronic and phononic degrees of freedom suggests strong el-ph coupling.\(^16\)

Despite considerable progress in pump-probe experimental studies, work on microscopic modeling of the influence of el-ph interactions on observables, such as time-dependent optical conductivity or Raman spectra, is very limited. Understanding the nonequilibrium dynamics of quantum many-body systems has, in fact, posed a theoretical challenge. Historically, theoretical attempts to model the time evolution of properties have either used quasi-equilibrium models such as \(T^*\) and \(\mu^*\) models\(^20\) to describe nonequilibrium excitations created by a pump-pulse\(^21\) or rate-equation approach based on the phenomenological Rothwarf-Taylor model\(^22\) to describe the recovery dynamics of the superconducting state. Recently, the time evolution of the optical conductivity has been studied within a microscopic model that treats the excitation and relaxation dynamics on the same footing.\(^23\) All these theories are suitable for pump-probe experiments with low excitation fluence wherein the superconducting condensate is merely perturbed but not destroyed. A picture of the dynamics of quasiparticles and the superconducting condensate in the photoinduced phase-transition regime\(^24\) which is impulsively driven by a high excitation fluence, has as yet been beyond reach.

Here we formulate a theory for the TR optical conductivity and TR Raman scattering in HTSCs in the regime of intermediate-to-high-intensity pump fluence. The theory is aimed to address directly the situation in which the superconducting condensate can be destroyed by a pump pulse. It is based on an effective-temperature model for different subsystems contributing to the response: electrons, hot phonons (i.e., out-of-plane, out-of-phase O-buckling \(B_{1g}\) phonons and half-breathing in-plane Cu-O-bond-stretching phonons) that are strongly coupled to electrons, and the cold lattice. The model phenomenologically includes the effect of the pump pulse but addresses in greater depth the electron-hot-phonon coupling based on a microscopic model Hamiltonian for \(d\)-wave superconductivity in HTSCs. This microscopic treatment goes beyond previous effective models for the normal state,\(^26\) allowing us to describe the quasiparticle dynamics in both the normal and superconducting states with the same approach. Within this unified model, the time evolution of the whole set of experimental measurables can be calculated in a streamlined way. Our first test of this approach considered the \(B_{1g}\) phonons as the only hot-phonon mode in the calculation of the TR spectral function for a very high pump fluence.\(^28\) In the present work, we include the half-breathing phonons as a second hot-phonon mode in the calculation of the TR optical spectroscopy. Importantly, the influence of excitation density on quasiparticle dynamics in HTSCs is also investigated. Our calculations show that,
in the superconducting state, in addition to the peak in the optical conductivity and Raman spectra due to the Drude response, there is another peak at higher frequencies. This high-frequency peak disappears when the system evolves into the normal state but recurs if the superconducting condensate is recovered, suggesting the significance of the superconducting gap in the TR optical properties.

The outline of the paper is as follows. In Sec. II, we lay down the effective-temperature model for a $d$-wave superconductor with electronic coupling to both $B_{1g}$ and half-breathing stretching-phonon modes. The time-dependent effective temperatures for the respective subsystems are evaluated depending on the strength of the pump fluence. With the obtained time dependence of effective temperatures, the time-resolved optical conductivity and Raman spectra and their pump-fluence dependences are presented in Secs. III and IV, respectively. Finally, a conclusion is given in Sec. V.

II. EFFECTIVE-TEMPERATURE MODEL

Let us consider a two-dimensional superconductor exposed to a laser field. The model Hamiltonian can be written as

$$H = \sum_{k\sigma} \xi_k c_k^\dagger c_k^\sigma + \sum_k (\Delta_k c_k^\dagger c_{-k}^\sigma + \text{H.c.}) + \sum_{q\nu} \hbar \Omega_{q\nu}$$

$$\times \left( b_{q\nu}^\dagger b_{q\nu} + \frac{1}{2} \right) + \frac{1}{\sqrt{N_L}} \sum_{k\nu\sigma} g_{\nu}(k, q) c_{k+q, \sigma}^\dagger c_k^\nu a_{q\nu} + H_{\text{local}}(\tau),$$

where $c_{k\sigma}^\dagger$ ($b_{q\nu}$) and $c_{k\sigma}$ ($b_{q\nu}$) are the creation and annihilation operators for an electron with momentum $k$ and spin $\sigma$ (and for a phonon with momentum $q$ and vibrational mode $\nu$, where $\nu = 1, 2$, representing the $B_{1g}$ and half-breathing modes, respectively), $A_{q\nu} = b_{q\nu}^\dagger + b_{q\nu}^\sigma$, $\xi_k$ is the normal-state energy dispersion, $\mu$ is the chemical potential, $\Delta_k = (\Delta_0/2)(\cos k_x - \cos k_y)$ is the $d_{x^2-y^2}$-wave-gap function, $N_L$ is the total number of lattice sites, and $g_{\nu}$ is the coupling matrix. Following the procedure sketched in Ref. 28, we arrive at a four-temperature model:

$$\frac{\partial T_e}{\partial \tau} = \frac{1}{C_e} \sum_{\nu} K_e(T_e, T_{ph\nu}) + \frac{P_e}{C_e},$$

$$\frac{\partial T_{ph\nu}}{\partial \tau} = \frac{K_e(T_e, T_{ph\nu})}{C_{ph\nu}} - \frac{T_{ph\nu} - T_i}{\tau_{ph\nu}},$$

$$\frac{\partial T_i}{\partial \tau} = \sum_{\nu} \left( \frac{C_{ph\nu}}{C_i} \right) T_{ph\nu} - T_i \frac{T_{ph\nu} - T_i}{\tau_{ph\nu}}.$$  

Here, $K_e$ is the el-ph-coupling kernel, which can be calculated from the model Hamiltonian (1) with the equation-of-motion approach. It is given by

$$K_e = \frac{4\pi}{N_L} \sum_{kq} g_{\nu}(u_{k\nu} u_{k-q\nu} - v_{k\nu} v_{k-q\nu})^2 \delta(E_{k-q} - E_k - \hbar \Omega_{q\nu}) \Omega_{q\nu} \left[ e^{(\beta_{ph\nu} - \beta_h)\hbar \Omega_{q\nu}} - 1 \right] (1 - f_{k-q}) N_{\Omega_{q\nu}},$$

where the Bogoliubov amplitudes are $u_k = [(1 + \xi_k/E_k)/2]^{1/2}$ and $v_k = \text{sgn}(\Delta_k) [(1 - \xi_k/E_k)/2]^{1/2}$ with $E_k = \sqrt{\xi_k^2 + \Delta_k^2}$ being the quasiparticle energy, and the Fermi-Dirac and Bose-Einstein distribution functions are given by $f_k = 1/(e^{(\beta_{ph\nu} - \beta_h)\hbar \Omega_{q\nu}} + 1)$ and $N_{\Omega_{q\nu}} = N(\Omega_{q\nu}) = 1/(e^{(\beta_{ph\nu} - \beta_h)\hbar \Omega_{q\nu}} + 1)$ with $\beta_{ph\nu} = 1/k_B T_{ph\nu}$, respectively. In Eq. (2), the specific heat for electrons per unit cell is found to be

$$C_e = \frac{\beta_h k_B}{N_L} \sum_k \left[ - \frac{\partial f(E_k)}{\partial E_k} \right] \left( 2 E_k^2 + \beta_h \Delta_k \frac{\partial \Delta_k}{\partial \beta_h} \right),$$

while that for each hot-phonon mode is given by

$$C_{ph\nu} = \frac{k_B}{4} \left( \hbar \Omega_{ph\nu} \hbar \Omega_{ph\nu} \right) \left[ \coth^2 \left( \frac{\hbar \Omega_{ph\nu}}{2} \right) - 1 \right]$$

in the Einstein-mode approximation $\Omega_{ph\nu} = \Omega_e$. Finally, $P_e$ is the power intensity (i.e., power per unit cell) for pumping electrons, and $\tau_{ph\nu}$ is the anharmonic-decay time of each hot-phonon mode.

Throughout this paper, we use a five-parameter tight-binding model to describe the normal-state energy dispersion, which is typical of optimally doped $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\nu}$ (Bi-2212):

$$\xi_k = -2t(\cos k_x + \cos k_y) - 4\nu(\cos k_x \cos k_y - \nu^2(\cos 2k_x + \cos 2k_y)) - 4\nu^2(\cos 2k_x \cos 2k_y - \mu),$$

where $\nu$ is the hopping integrals are $t_1 = t' = -0.2749$, $t'' = 0.0872$, $t''' = 0.0938$, $t'''' = -0.0857$, and $\mu = -0.8772$. The absolute energy of $t$ is 150 meV. A feature of this dispersion is a flat band with a saddle point at the $M$ points of the Brillouin zone. The temperature dependence of the $d$-wave-gap magnitude is given by

$$\Delta_0(T_c) = \Delta_0(0)[\tanh(\pi/2) \sqrt{\alpha(T_c/T_e - 1)}],$$

where $\alpha = \Delta_0(0)/(k_B T_e)$. In our calculations, we set $\Delta_0 = 30$ meV, the critical temperature $T_c = 104 K$ (from the setting of $T_e = 0.06r$ for simplicity), the specific-heat jump at $T_c$ as $\alpha = \Delta C_e/C_e \approx 1.43$, and $a = 2/3$. We take the anisotropic el-ph coupling in the form given in Refs. 3 and 31 with $\Omega_{1} = 45$ meV and $g_{1}^{(0)} = 90$ meV and $\Omega_{2} = 70$ meV and $g_{2}^{(0)} = 120$ meV with $t_{\nu,1} = t_{\nu,2} = 880$ fs and $C_{\nu,1} = C_{\nu,2} = 0.2C_i$. The pump is represented by a Gaussian pulse $P = P_0 e^{-t^2/(2\Omega^2)}$ with a full width at half maximum (FWHM) of 2.35\Omega. Hereafter, we assume implicitly $h = 1$ and set $\sigma = 4.4$ fs, giving a FWHM of about 10.34 fs. This value is smaller than the commonly used experimental values of about 30–50 fs but is indeed close to that value of 12 fs used in the recent TR experiment on $\text{YBa}_2\text{Cu}_3\text{O}_{7-\nu}$.

We believe that this variation will not affect the qualitative physics as will be presented below. We take the number of $k$ points to be $40 \times 40$ in the Brillouin zone for the temperature evolution and use 256 $\times$ 256 for the TR optical conductivity and Raman-scattering spectral function. All calculations are done with the system initially in the superconducting state for $T < T_c$. Figure 1 shows the time evolution of the effective temperature for each subsystem for a large pump-power intensity $P_0 = 0.436 \mu W$ [Fig. 1(a)] and an intermediate value of $P_0 = 0.022 \mu W$ [Fig. 1(b)]. These values of pump power correspond to 120 $\mu J/cm^2$ and 6 $\mu J/cm^2$ of pump fluence in Bi-2212, respectively, assuming a 60-nm optical-absorption depth. Starting from the initial temperature $T_e = T_{ph\nu} = T_i = \frac{4\pi}{N_L} \sum_{kq} g_{\nu}(u_{k\nu} u_{k-q\nu} - v_{k\nu} v_{k-q\nu})^2 \delta(E_{k-q} - E_k - \hbar \Omega_{q\nu}) \Omega_{q\nu} \left[ e^{(\beta_{ph\nu} - \beta_h)\hbar \Omega_{q\nu}} - 1 \right] (1 - f_{k-q}) N_{\Omega_{q\nu}},$
significantly due to the opening of the superconducting gap.

Further energy relaxation is then slowed down with the kink recurring during the cooling stage [see the inset of Fig. 1(a) and 1(b)] for both power intensities. In addition, for $\tau = -440$ fs and $-11$ fs at which the material is superconducting and $\Delta_0 \approx 30$ meV, we observe that $\sigma_1(\omega)$ exhibits a broad peak at about $\omega = 2\Delta_0 + \Omega_{ph,1}$. (The specific location may be affected by several factors although $2\Delta_0 + \Omega_{ph,1}$ plays a substantial role.) Our observation is consistent with an earlier study of optical conductivity in the thermal-equilibrium state of HTSCs. In contrast, no

III. TIME-RESOLVED OPTICAL CONDUCTIVITY

Within the Kubo formalism, the real part of the TR optical conductivity is given by

$$\sigma_1(\omega) = -\frac{e^2 \text{Im} \Pi(\omega)}{\omega},$$

where

$$\text{Im} \Pi(\omega) = -\frac{2\pi}{N_L} \sum_k \left( \frac{\partial \mathcal{F}_k}{\partial k_i} \right)^2 I_W(k, \omega)$$

and

$$I_W(k, \omega) = 2i \int d\tau' \text{Tr} \text{Im} [\hat{F}^{+}(k, \tau') \hat{A}(k, \tau')] e^{i\omega \tau'}. \hspace{1cm} (10)$$

Here, $\hat{A}(k, \tau')$ and $\hat{F}(k, \tau')$ are the Fourier transforms of the TR spectral functions $\hat{A}(k, \epsilon)$ and $\hat{F}(k, \epsilon)$, respectively. In the derivation of Eq. (9), we have used the Hilbert transform

$$\hat{g}(k, i\omega_n) = \int_{-\infty}^{\infty} d\epsilon \hat{A}(k, \epsilon) \frac{1}{i\omega_n - \epsilon}$$

with the single-particle spectral function

$$\hat{A}(k, \epsilon) = -\frac{1}{\pi} \text{Im} [\hat{g}(k, i\omega_n \rightarrow \epsilon + i\delta)], \hspace{1cm} (11)$$

where the Green’s function $\hat{g}$ and $\hat{A}$ are $2 \times 2$ matrices in the Nambu space. Since this spectral function as calculated with the method of Ref. 28 is a function of the effective electronic temperature, which is time dependent (see the discussion in Sec. II), it is time resolved. Therefore, the optical conductivity and the Raman spectra as discussed in the next section are also time dependent.

Figure 2 shows the time evolution of the real part of the optical conductivity $\sigma_1(\omega)$ at several selected time delays. From Fig. 2, one can see that at all time delays, the optical conductivity shows the well-known Drude peak at $\omega = 0$ due to the nodal quasiparticles for the $d$-wave gap symmetry. In addition, for $\tau = -440$ fs and $-11$ fs at which the material is superconducting and $\Delta_0 \approx 30$ meV, we observe that $\sigma_1(\omega)$ exhibits a broad peak at about $\omega = 2\Delta_0 + \Omega_{ph,1}$. (The specific location may be affected by several factors although $2\Delta_0 + \Omega_{ph,1}$ plays a substantial role.) Our observation is consistent with an earlier study of optical conductivity in the thermal-equilibrium state of HTSCs. In contrast, no

**FIG. 1.** (Color online) Time evolution of the effective temperatures of electrons $T_e$ (red solid line), $B_{1g}$-phonon mode $T_{ph,1}$ (blue dotted line), half-breathing-phonon mode $T_{ph,2}$ (black dashed line), and cold lattice $T_l$ (magenta dashed line) for the powers (a) $P_0 = 0.436 \mu W$ and (b) $P_0 = 0.022 \mu W$. The inset in (a) shows an enlarged view of $T_e$ rising up above $T_c$, while that in (b) shows an enlarged view of $T_e$ cooling down below $T_c$.

17 K, the electron temperature $T_e$ increases rapidly after photoexcitation, and the superconductor is driven into the normal state while exhibiting a kink structure at $T_e$ [see the inset of Fig. 1(a) and 1(b)] for both power intensities. In addition, $T_e$ shows a very narrow peak for the large $P_0$ [see Fig. 1(a)], with a broader peak for the intermediate $P_0$ [see Fig. 1(b)], due to the fact that the highest temperature achieved by electrons is very sensitive to the pump fluence. In both cases, the hot-phonon subsystems are first heated up through their coupling to the photoexcited electrons, and after reaching their maximum temperature, they cool down by dissipating energy into the cold lattice through anharmonic coupling. A noticeable difference between the large and intermediate pump fluences is that in the latter case, the superconducting state recovers more rapidly (i.e., $T_e \approx T_c$) in a very short time (~650 fs) with the kink recurring during the cooling stage [see the inset of Fig. 1(b)]. Further energy relaxation is then slowed down significantly due to the opening of the superconducting gap.

---

**FIG. 2.** (Color online) Real part of the time-resolved optical conductivity at several different time delays for (a) $P_0 = 0.436 \mu W$ and (b) $0.022 \mu W$. The numbers in parentheses are $T_e$.
peak at \( \omega = \Omega_{\text{ph},2} \) is observed (a signature of the coupling between electrons and the half-breathing mode along the nodal directions). This is due to the fact that the coupling between electrons and the \( B_{1g} \)-phonon mode is the strongest at the \( M \) points at which the van Hove singularity is also located. This is further verified by the observation that no such peak appears when the el-ph coupling is turned off in the initial superconducting state \( T_c = 17 \) K (red solid line in Fig. 2). After photoexcitation, the superconducting gap with its time dependence encoded in the effective electron temperature \( \Delta_0(T_c) \) is decreased, and the high-frequency peak shifts toward lower frequencies, merging into the zero-frequency Drude peak in the normal state. For large \( P_0 \), the Drude peak remains for the whole time-delay range being simulated. However, for intermediate \( P_0 \), once the superconducting condensate recovers, the \( [2\Delta_0(T_c) + \Omega_{\text{ph},1}] \)-peak recurs—a reentrant behavior. The absence of the peak at \( \Omega_{\text{ph},2} \) is robust with the time delay.

IV. TIME-RESOLVED RAMAN-SCATTERING SPECTRUM

The time-resolved Raman-scattering intensity is calculated via a simple relation\(^{34} \) from the imaginary part of the Raman-response function. In the bare-vertex approximation,\(^{35,36} \) it is found as

\[
\text{Im} \chi(i\Omega_m \to \omega + i\delta) = -\frac{2\pi^2}{N_L} \sum_k \gamma_k^2 I_\gamma (k, \omega), \tag{13}
\]

where

\[
I_\gamma (k, \omega) = 2i \int d\tau \text{TrIm}[\hat{\varepsilon}_0 \hat{F}^{\gamma}(k, \tau) \hat{\varepsilon}_3 \hat{A}(k, \tau)] e^{i\omega \tau}. \tag{14}
\]

Here, \( \gamma_k \) is the nonresonant bare Raman vertex given by \( \gamma_k = \gamma_k \hat{\varepsilon}_3 \hat{\varepsilon}_5 \) with \( \hat{\varepsilon}_3 \) being the Pauli matrix and \( \gamma_k = \sum_{\alpha,\beta} e^S_{\alpha,\beta} \hat{\varepsilon}_k^{\alpha,\beta} e^{\dagger}_k^{\alpha,\beta} \) are the polarization unit vectors of the incident and scattered photons, respectively, and \( \xi_k \) is the electronic-normal-state dispersion of the conduction band.

Figure 3 shows the time evolution of the Raman-scattering spectrum. When the electron-hot-phonon coupling is switched off, the Raman spectrum rises with \( \omega \) and has a large peak at twice the gap, \( 2\Delta_0 \), at the initial temperature (red solid line in Fig. 3). A small shoulder in the curve around 90 meV arises due to the van Hove singularity. In the presence of the electron-hot-phonon coupling, the superconducting gap function is renormalized, shifting the original \( 2\Delta_0 \) peak to lower frequencies. Simultaneously, another peak develops at \( 2\Delta_0 + \Omega_{\text{ph},1} \), but no peak develops at \( \Omega_{\text{ph},2} \) for the same reason as in the case of the optical conductivity (see Fig. 2). After photoexcitation, this double-peak structure evolves into a very broad peak as the system enters the normal state. For large \( P_0 \), this broad peak remains for a few picoseconds. However, for intermediate \( P_0 \), once the superconducting state recovers, the double-peak structure appears again. This result is fully consistent with our calculations of the TR optical conductivity described above.

V. CONCLUSION

We have presented a theory for the time-resolved optical conductivity and Raman spectra, based on the TR spectral function that we have recently formulated for HTSCs. Our calculations show that the signature of the electron-\( B_{1g} \)-mode coupling in the TR optical conductivity and Raman spectra is more pronounced than the consequence of the coupling between electrons and the half-breathing mode. This is the result of a concurrence of the anisotropy of the el-ph coupling, band structure, and \( d \)-wave energy gap in HTSCs. Even more interestingly, this signature also shows a reentrant behavior in concurrence with the superconducting condensate, which can be controlled by the pump fluence. The observation of the broad peak in the TR Raman spectra and its reentrant behavior provides direct evidence of the el-ph coupling.
